PREFACE TO THE TENTH EDITION.

THE revision of the ninth edition of this work has been, on the whole, more thorough than that of its predecessors, with a view to bringing all subjects up to date and adapting them to the requirements of both student and practitioner. But little space has been devoted to moot points, while the sphere of usefulness of the volume has been, it is confidently believed, enhanced by a detailed consideration of the more practical aspects of medicine—*e. g.*, etiology, diagnosis and treatment. To this end, an earnest effort has been made to improve the arrangement of the subject matter, so as to facilitate the reader's grasp of the natural history of disease, thus enabling him to observe the logical connection between cause and effect, as well as to acquaint him with the developmental stages in the individual pathologic processes described and their symptomatic manifestations.

These changes, together with the addition of a considerable amount of new matter, it is hoped render the present edition a systematic and well-ordered statement of our present-day knowledge of practical medicine. In the fields of diagnosis and differential diagnosis cognizance has been taken of the basic principle that their elucidation requires the clinician and student to draw constantly upon allied branches, such as chemistry, physics, physiology, pathology, morbid anatomy, and bacteriology. Unquestionably, the most successful diagnostician is he who at the bedside aims to trace clinical phenomena back to the structural changes or other causes which produce them by the aid of his knowledge of these cognate subjects and, more particularly, morbid physiology.

Under treatment, personal experience and observation have been made prominent, but not to the exclusion of the methods widely sanctioned by those masters who have adorned the subject of the rational treatment of disease with their contributions. Emphasis has been, as in previous issues of this work, also given to prophylactic measures and causal therapy—the two leading departments in the scientific management of individual diseases. The section on Tropical Diseases has been again enlarged in consequence of the growing interest in the study of these complaints, and the notable advances that have resulted from these investigations, as well as the increasing number of physicians who are entering upon the practice of medicine in our tropical posses-

sions. Among the conditions and diseases newly discussed in this volume and scattered throughout its pages are: Abortive type of plague, masked chlorosis, polycythemia hypertonica (erythrocytosis), blocked pleurisy, angina major, angina minor, angina abdominis, hour-glass stomach, appendix dyspepsia, fatty liver, heat cramps, serous meningitis, tic, and psychasthenia.

New and "rewritten matter" also includes the following: Coleman on milk-sugar in typhoid fever, Chantemesse's serum in typhoid fever, Brudzinski's sign in cerebrospinal meningitis, tonsillectomy in acute articular rheumatism, Falk and Tedesko's test in chronic tuberculosis, artificial pneumothorax in pulmonary tuberculosis, Nastin treatment of leprosy, appendicostomy in chronic amebic dysentery, Ehrlich's remedy in sleeping sickness, salvarsan ("606") in syphilis and in malaria, Bass' method of examining feces in uncinariasis, Wassermann's reaction in syphilis, Grawitz's treatment of pernicious anemia, transfusion of blood in pernicious anemia, autoserotherapy in serofibrinous pleurisy, Holmgren's treatment of serofibrinous pleurisy, Broadbent's sign in aortic regurgitation, Oertel cure in chronic myocarditis, Gordon's method of determining myocardia, Klotz's experiments on arteriosclerosis, salt-free diet in arteriosclerosis, colon bacillus producing ulcer of stomach and duodenum, glycyltryptophan test in cancer of stomach, Goodman's modification of Solomon's test in cancer of stomach, Boas' method of diagnosis in intestinal catarrh, hemohepatogenous jaundice, chronic family jaundice, chronic cholecystitis, autoserotherapy in ascites, Boston's test for albuminuria, Martinet's method of estimating acidity of urine as a basis for treatment, Schapira's test for permeability of kidney, McBride's treatment of alcoholism, neuritis, neuralgia, anterior poliomyelitis, tumors of spinal cord, aphasia, cerebral palsies of children, Breur and Freud's theories of hysteria, and analytical or cathartic method of treating hysteria.

If the claims to professional favor of the previous editions shall be maintained by the present volume, the author shall be more than gratified. My best thanks are due to Dr. Chas. S. Potts, for his thorough and masterly revision of the section on Nervous Diseases, and to Dr. H. Leon Jameson, for kind aid in collecting new material and proof-reading. Finally, grateful acknowledgement is cheerfully extended to the publishers for much courtesy and kindly interest while the volume was passing through the press.

JAMES M. ANDERS.

PHILADELPHIA,
1605 WALNUT STREET, August, 1911.

PREFACE.

THIS work is meant to introduce the student to the present state of our knowledge of the practice of medicine in general and of the diagnosis, differential diagnosis, and treatment of disease in particular. The historic development of the subjects treated has been either briefly given or intendedly omitted, since this scarcely falls within the scope of a practical treatise on medicine. Although the book as a whole is submitted to the critical judgment of a learned profession, it may be pardonable to emphasize, provisionally, a few features pertaining to the mode of treating the separate subjects, or the arrangement of the material under the latter—to indicate some of the more salient lineaments, so to speak, in the general design. Since in medical schools it is taught from a separate chair, the pathology (special) of the individual affections has almost invariably been taken up before the etiology; from this point the student will find the story of each affection a continuous one. The practitioner, however, must ever aim to associate the clinical symptoms with the morbid lesions.

Under special etiology the bacteriology has been prominently mentioned, since we owe to it the rapid progress that is being made in the study of the causation of disease.

The differential diagnosis has in many instances been tabulated—an ear-mark that I confidently believe will be found especially helpful. It may be stated that not less than fifty-six diagnostic tables are scattered throughout the work, and that by far the greater number of these are my own.

Such formulæ have been introduced into the text, and only such, as a more or less extended experience has shown to be possessed of real therapeutic importance. Whilst these, and all additional points relating to the treatment of the single affections, may serve as guides, particularly to the beginner, I fully appreciate how often the practising physician is

placed in a position in which he is compelled to form a therapeutic judgment for himself. Whenever the dosage is stated, the metric equivalent is placed in parentheses, the number of grams being stated in round numbers ($\bar{3}j$ —4.0; $\bar{3}j$ —32.0) in order to render it of greater practical value. In all instances, however, in which this would involve an important difference in quantity the exact decimal figures are given. A considerable variation from the usual classification of diseases may be observed, but this is accounted for in the text wherever it occurs.

Preference has been given to the modern orthography and terminology, not only because it is more euphonious, but also because of its adoption by the standard lexicographers.

I have gleaned without stint from medical literature with a view to bringing the book up to date, and if I have failed to give full credit in every instance, my grateful acknowledgments are here due and are cheerfully made. The chief results of my personal experience and observation, extending over a period of two decades, and derived from both hospital and private practice, will also be found upon these pages.

I wish to thank Prof. W. C. Hollopeter, who has written some of the articles upon the diseases of children, as measles, chicken-pox, mumps, whooping-cough, and the acute diarrheas, and who has kindly aided in the preparation of those upon diphtheria and scarlatina.

My cordial thanks are due also to Dr. C. L. Furbush for kind aid in preparing some of the illustrations, to Doctors Robert N. Willson, Howard S. Anders, and Geo. W. Pfromm for valuable assistance while the work was passing through the press, and to Dr. A. M. Davis for preparing the index.

JAMES M. ANDERS.

CONTENTS.

PART I.—INFECTIOUS DISEASES.

| | PAGE |
|--|------|
| Typhoid Fever | 17 |
| Paratyphoid Fevers | 66 |
| Typhus Fever | 67 |

PART I.

INFECTIOUS DISEASES.

TYPHOID FEVER.

(*Enteric Fever; Abdominal Typhus; Ileo-typhoid; Nerven Fieber.*)

Definition.—An acute infectious disease of which the definitive cause is the specific bacillus of Eberth (*bacillus typhosus*). It is characterized, pathologically, by hyperplasia and sloughing of Peyer's patches and the solitary follicles of the intestines coupled with parenchymatous changes in the principal viscera, and clinically by its gradual onset, peculiar temperature-curve, swelling of the spleen, rose-colored spots, diarrhea, tympanites, sero-reaction, and a liability to certain complications (intestinal hemorrhage, perforation, etc.). The disease is a bacteremia, and typhoid infection is no longer an anatomic entity, and does not always produce typical typhoid fever.

History.—Although known beyond the reach of tradition, typhoid fever was clearly distinguished from typhus at a comparatively recent date. Louis of Paris in 1829 proposed the term *typhoide*, but it remained for Gerhard of Philadelphia to discriminate typhoid from typhus fever as the result of his own precise clinical observations. His account of the disease was ably corroborated by the writings of E. Hale and James Jackson, Sr. (1838, 1839). Later, Shattuck of Boston and Jenner of London made important contributions to the subject. Shattuck's experiments on typhus and typhoid fevers at the London Fever Hospital in England, and Alfred Stillé's studies of the former affection in Dublin and Naples, and of the latter in Paris, increased greatly our knowledge of these diseases. As a result of the labors of the above-mentioned American authors the true nature and identity of typhoid fever were appreciated in America at an earlier day than in either France or England.

Briefly, the decade from 1840 to 1850 witnessed the overthrow of erroneous notions concerning the similarity of typhoid and typhus fevers, on the one hand, and the establishment of their points of dissimilarity on the other.

Pathology.—The lesions produced by typhoid fever may conveniently be divided into two groups: (1) Primary lesions, due to the direct effect of the special bacillus upon the lymph-follicles of the intestines, the mesenteric and other lymph-glands, the gall-bladder, and the spleen. Typhoid septicemia without localizing lesions is also a recognized form of the disease. (2) Secondary lesions, due chiefly to the

indirect effect of the typhoid bacillus and secondary infection, for the occurrence of which the essential lesions furnish the golden opportunity.

(1) The primary morbid changes in the Peyer's patches and solitary glands of the intestines are divided, usually, into four stages:

(a) **The Stage of Infiltration.**—The lymph-follicles become engorged (hyperplasia), particularly Peyer's glands in the ileum and near to the valve, and, to a lesser extent, in the lower part of the jejunum. Frequently the solitary glands in the small intestines, the colon, and rarely the rectum, become similarly infiltrated. In mild cases a few Peyer's patches in the lower part of the ileum are alone the seat of infiltration and subsequent changes. The follicles are grayish-white in color, and may project from 3 to 5 mm. or more. Rarely the solitary glands, which vary in size from a mustard-seed to a large pea, also become prominent and show a bold attempt at pedunculation.

The *histologic changes* at first consist in a marked dilatation of the capillary blood-vessels, which later are more or less compressed (as a consequence of cell-infiltration), giving to the follicles their whitish, anemic appearance. The cellular elements partake of the nature of lymph-corpuscles. Some of these cells are larger and are epithelioid in character, with ten or more nuclei. The mucosa and muscularis adjacent to the glandular structures may be similarly infiltrated.

From the eighth to the tenth day the stage of infiltration terminates either in resolution (rare) or in necrosis and sloughing. The infiltrated cells may undergo granular or fatty degeneration, followed by absorption. This process—resolution—during its progress produces pitting of the swollen follicles. In consequence of these minute points of necrosis the plaques now present a characteristic reticulated appearance (plaques à surface réticulée). When resolution occurs accompanied by destruction of the follicles, small hemorrhages may take place into the glandular structure. These hemorrhages may occasion pigmentary deposits in the follicular depressions, giving rise to the so-called "shaven-beard" appearance.

(b) **Necrosis or Sloughing.**—In all save the milder grades of cell-infiltration the hyperplasia of the lymphatic tissue cannot subside before necrosis occurs. The latter process results partly from compression and choking of the blood-vessels by the cell-proliferation, and partly from the direct action of the typhoid bacillus, leading to so-called anemic necrosis. Thus, necrotic crusts (sloughs) are formed, which are gradually separated and cast off. While not all of the glands of Peyer which are the seat of cellular infiltration undergo subsequent necrosis, as a rule those situated in the lower portion of the ileum do, and show the process in its completest development. The depth to which the necrosis extends is quite variable. It may involve only the most superficial layers of the mucosa, or it may extend in depth till it reaches, or even perforates, the outer or serous coat; but usually this work of destruction does not dip below the submucosa or muscularis. The necrosed portions become detached—a process that proceeds from the periphery toward the center—leaving behind the typhoid ulcer. The stage of necrosis and sloughing begins between the eighth and tenth days, and ends on or about the twenty-first day.

(c) **Stage of Ulceration.**—The size and shape of the ulcers corre-

spond exactly to the necrosed areas in these respects. A single gland of Peyer generally presents several ulcers of irregular outline separated by strips of mucous membrane. Rarely, the entire plaque is implicated, in which case a large oval ulcer is the result, and at the lower end of the ileum the ulcers often coalesce until they almost encircle the bowel. The ulcers of the solitary glands assume a rounded form. The character of the floor of the ulcer will vary with the character of the intestinal coat which forms its base, though usually it is clean and smooth. The edges are usually irregular, engorged, soft, and frequently overhanging. In the lower segment of the ileum ulcers may be numerous, and in about 25 per cent. of the cases the typhoid ulcers are found in the large intestines—*i. e.*, in the cecum and colon.

Hemorrhage usually results from erosion of a vessel—an accident which is occasioned by the separation of the sloughs—but small bleedings may take place from the swollen, hyperemic edges of an ulcer. *Perforation* of the bowel occurs in a small percentage of cases (about 6 per cent.). J. A. Scott has pointed out two varieties: (*a*) Circular, pin-point in size, due to a perforative necrosis (common), and (*b*) a large aperture (as the result of extensive necrosis) ranging in size from the finger-tip to 3 cm. in diameter. The perforations may be multiple, though they are usually single. The small, deep ulcers are more apt to lead to complete perforation than larger ones, and the site of the orifice is usually in the course of the lower third of the ileum. The lesions of peritonitis invariably follow. Perforation of the large bowel is exceedingly rare. Exceptionally, the appendix is the seat of ulcer. Localized abscesses have been found under these circumstances. During the stages of necrosis and ulceration a catarrhal state of the mucosa of the intestines exists. The diarrhea which usually accompanies typhoid is ascribable, in part at least, to the catarrhal state of the large bowel.

(*d*) **Healing** follows promptly upon the formation of the ulcer. At first a granular tissue covers its floor. The mucous membrane is replaced, including the glandular elements and epithelial layer, and, as in the stage of necrosis and sloughing, so the healing process advances inward from the border of the ulcer. Indeed, it is this process that dislodges the necrotic crust. Occasionally, ulcers are seen extending in one direction while healing in another. The cicatrix formed by the healing of an ulcer presents a smooth and often pigmented surface.

The stages thus far described do not, strictly speaking, follow one another, since two or more may be illustrated at once by a group of ulcers occupying the intestine. When death occurs during a relapse fresh ulcers are observed by the side of those partially healed.

The Mesenteric Glands.—Changes in the mesenteric glands occur simultaneously with those in the intestines, and those situated opposite to the lower third of the ileum, the portion of the bowel showing the most extensive ulceration, are most profoundly involved. Hyperemia, and later swelling due to cell-infiltration, are among the earliest changes, and correspond with the lesions noted in the intestines (*vide supra*). The mesenteric glands exhibit great variations in size, ranging, as they do, from that of a pea to a hen's egg. Their color appearance is a grayish red. Resolution commonly occurs, but, if it does not, then necrosis of the central portion (due, most probably, to the same causes that

produce necrosis of the intestinal lymph-follicles) occurs. Le Conte¹ believes that perforation of the capsule of the glands, when it occurs, is due either to the presence of the staphylococcus or streptococcus or to thrombosis of the larger vessels of the mesentery outside of the glands. Still other glands become hyperemic and swollen (retroperitoneal, bronchial); but these usually tend toward resolution.

The Spleen.—With rare exceptions the spleen becomes enlarged in typhoid fever. At first hyperemic, the tissue then grows soft and granular, and at times is almost diffuent on section. Infarction is not a rare occurrence and may lead to suppuration. Keen has searched the literature and found only 9 cases of abscess. In rare instances, either spontaneously or as the result of injury, the spleen may rupture, and the records of 2000 post-mortems at the Munich Pathologic Institute furnish 5 cases. Perisplenitis rarely occurs (*vide* Spleno-typhoid, p. 45).

Gall-bladder.—The *gall-bladder* may show catarrhal inflammation, and rarely a croupous, diphtheritic, or ulcerative inflammation leading to perforation. Westcott has tabulated 30 cases of typhoid infection of the gall-bladder that resulted in perforation. Chiari's² and Flexner's³ figures show that typhoid bacilli are found in the gall-bladder in more than 50 per cent. of the fatal cases. Chiarolanza⁴ found that typhoid bacilli injected intravenously reached the gall-bladder in 17 out of 23 cases, entering through the capillaries of the mucosa and submucosa. (*Vide* Acute Infectious Cholecystitis.)

Mallory has shown that the typhoid bacillus produces a toxin which causes proliferation of the endothelial cells along the line of absorption from the intestines, both in the lymphatics and blood-vessels. These cells increase in size and number, and manifest phagocytic properties.

(2) **Secondary Lesions due Chiefly to the Continued Fever and to Secondary Infections.**—The lesions in other organs are of subsidiary importance, and are, for the most part, secondary in nature, though we cannot draw a sharp line of distinction between these lesions and those that are primary.

The *liver* early becomes hyperemic, and later is softer and paler than is natural. Handford has described necrotic areas, and Wagner minute lymphomata. Infarction and abscess occur in rare instances. Mesenteric abscess and perforative appendicitis may be followed by pylephlebitis.

The microscope reveals parenchymatous and granular degeneration. The cells contain an abundance of fat, whilst their nuclei have lost, in great part, their outline.

The *kidneys*, like the liver, exhibit parenchymatous degeneration. They are somewhat pale-looking, are cloudy on section, and slightly swollen, and under the microscope granular and fatty degeneration of the epithelial cells of the convoluted tubules is observed. More rarely the lesions are those of *acute hemorrhagic nephritis*. Small areas of round-cell infiltration may develop late in the course of typhoid, and these may present an appearance similar to lymphomata or may undergo softening and suppuration, giving rise to miliary abscesses. The mucous membrane of the pelvis of the kidney is not infrequently the seat of a mild grade of catarrh, and, rarely, of diphtheritic inflammation.

¹ *Jour. Am. Med. Assoc.*, Oct. 22, 1904. ² *Prag. med. Woch.*, 1903, No. 22.

³ *Johns Hopkins Hosp. Reports*, vol. v.

⁴ *Ztschr. f. Hygiene u. Infektionskr.*, 1908, lxi., 1.

Typhoid cystitis is still more common, and the bladder may also be the seat of diphtheritic inflammation. Rarely orchitis is encountered. On making cultures from sections of the kidneys not a few observers have been able to demonstrate the specific bacillus of typhoid, particularly in the softened areas.

In the *lungs* are found morbid lesions in nearly all cases of typhoid fever, and belonging to the essential pathologic processes is bronchitis, due to a congested and catarrhal state of the bronchial mucous membrane. The lesions of lobular pneumonia present a complicating condition in many instances; those of lobar pneumonia also may be present, though less commonly. The so-called *hypostatic congestion* is often found, but is, I think, less frequent than is supposed by many authors. *Embolie infarctions*, having their origin in thrombi occupying the right side of the heart, are sometimes present. Gangrene may also occur.

Pleurisy is rarely met with. It is generally of the plastic variety, although empyema occurred in nearly 2 per cent. of the Munich cases. The initial lesion may be pleuritic. (*Vide* Pleuro-typhoid, p. 45.)

The *larynx* and the *pharynx* may manifest changes. Ulcers have been observed on the epiglottis and posterior wall of the larynx, and I have more than once seen them on the pharynx (*Pharingo-typhoid*). When situated in the larynx they may extend in depth till they reach the perichondrium, causing perichondritis, with or without edema of the larynx. Typhoid bacilli have been found in the ulcers (Eichhorst). Catarrhal, or even croupous, pharyngitis may occur, and a swelling of the follicles of the pharynx and base of the tongue is to be noticed in many cases. True aphthous changes, affecting the mouth and pharynx, may be present as a secondary event. The tonsils may present ulcers (*Tonsillo-typhoid*.) The *mucosa of the stomach* is sometimes congested, and may be the seat of typhoid ulcers, although this is rare.

Peritonitis is always found in fatal cases in which the bowel has been perforated. The condition is a general one, save in the rare instances mentioned below, and there is usually much fibrino-purulent effusion present. Diffuse peritonitis may be present without perforation, and results sometimes from a localization of the typhoid poison in the peritoneum, from rupture of suppurating mesenteric glands, and from direct extension of intestinal inflammation to the peritoneum.

The *heart* may be the seat of morbid changes. Acute endocarditis may be a very rare complication, while pericarditis occurs relatively more often—viz. in 14 of the Munich post-mortems before mentioned. Myocarditis is a common event, the cardiac muscle exhibiting parenchymatous and, less commonly, hyaline degeneration, and the latter change sometimes leads to sudden rupture of the muscular fibers, with a fatal result (myocardite ségmentaire). It is, however, a significant fact that in many instances, even of the severest type, the cell-fibers may show slight, if any, noticeable change. Out of 48 cases, 16 showed granular or fatty degeneration, and 3 a proliferative endarteritis in the small vessels (Dewevre).

The *arteries* have, in a number of instances, been found to be the seat of two forms of arteritis (Barié): (a) Acute obliterating arteritis and (b) partial arteritis. These conditions may affect the smaller ves-

sels, particularly those of the heart, but they occur most commonly in the arteries of the lower extremities. Thrombi are found in the right chambers of the heart and in the veins—most frequently in the femoral, and less often in the cerebral, sinus. According to Flexner, thrombi may be caused by auto-agglutination of the red cells.

The *voluntary muscles* undergo parenchymatous and, occasionally, a hyaline change, though this is not a feature peculiar to typhoid fever. The latter form of degeneration does not affect the whole muscle, but only certain fibers, and, as a rule, the recti abdominis, the diaphragm, the adductors of the thigh, and the pectorals are the seats of the lesion. The parts affected are pale and possess a grayish, waxy lustre. Histologically, the process implies the transformation of the muscular fibers, and especially the cement substance, into a homogeneous, pliable mass. Regeneration of the fibers occurs during convalescence. Hemorrhages into, and rarely abscesses in, the intermuscular tissue occur.

The *nervous system* presents no gross lesions, if we except meningitis, the latter occurring as a complication; but it is exceedingly rare, having been present in only 11 of the 2000 Munich cases. In a few instances large cerebral hemorrhages have been met with, but these are apparently coincidental, while capillary hemorrhages into the cortex may be numerous. Meningeal hemorrhages may also occur. Slight edema of the cerebral cortex has been noted. The peripheral nerves are not infrequently the seat of parenchymatous change, with or without local neuritis, and the ganglia of the trunks of the vagi exhibit an inflammatory change which Levin believes is the cause of the laryngitis, pharyngitis, pharyngolysis, and arrhythmia sometimes observed.

The *blood* shows few important alterations. The red blood-corpuscles are relatively increased during the febrile period and markedly diminished during convalescence, but the great loss of water during the former period and a reabsorption during the latter will explain these interesting facts (Henry). Leukocytosis is absent (*vide infra*, p. 40).

Etiology.—Bacteriology.—The bacterium which is the specific cause of typhoid fever was discovered by Eberth, whose researches were later confirmed by the investigations of Gaffky and others.

General Characters.—It is a short, thick bacillus, about three times as long as it is broad, with rounded ends (Fig. 1). It is motile, due to the presence of cilia, and when stained, exhibits vacuolations that have been mistaken for spores. It is easily stained with all the anilin dyes.

Characteristic Growth.—Upon gelatin plates it develops in grayish translucent colonies with irregular borders and ridged surfaces. Upon agar the growth is not characteristic; upon the potato, especially if it has been rendered slightly acid, it forms a perfectly transparent growth that is only evident as a slight apparent increase of moisture upon the surface, and as offering a greater resistance to the point of the needle when scraped across it. It neither coagulates milk, liquefies gelatin, nor produces indol. The organism never forms spores. Moreover, the bacillus has no greater powers of resistance than the ordinary bacteria.

Experimental Typhoid.—Inoculated into lower animals, the bacillus frequently causes fatal results without producing the lesions characteristic of typhoid in human beings, although occasionally typical typhoid ulcers have been found. The susceptibility of lower animals, though nor-

mally slight, can be increased by preliminary injections of saprophytic bacteria, this result having been obtained by Alessi when he exposed animals to the gases produced by putrefying matters. It has been found that the ulcerative intestinal lesions produced by the inoculation of the bacilli or their toxins in large quantities into the blood of rabbits may also be caused by other bacteria, including the bacillus coli commune. Metchnikoff,¹ however, has administered foods contaminated with weak dilutions of bacillus-infected feces to chimpanzees; they contracted characteristic typhoid fever.

FIG. 1.—Typhoid bacilli with flagella; $\times 1000$.

Usually, in making a *bacteriologic diagnosis* the typhoid bacillus is to be differentiated from those organisms that morphologically resemble it and present almost identical characteristics upon various culture-media, such as the bacillus of Shiga, paracolon bacilli, and the bacillus coli communis. These organisms can now be separated from the bacillus of Eberth, bacteriologists having pointed out the fundamental differences between these related forms. Smith and Tennant, in a study of the 1898 epidemic of typhoid in Belfast, failed to find typhoid bacilli in the water-supply, but were able to isolate varieties of the bacillus coli communis.

The real poison of typhoid fever is most probably a ferment (?) secreted by the bacillus—*typho-toxin*; and Brieger has extracted the latter agent, finding that it produces the fever, nervous symptoms, and the other manifestations characteristic of the affection.

Distribution in the Body.—The bacillus has been found in the intestinal tract, the lymph-glands, the contents of the intestine, the spleen, the liver, the gall-bladder, the rose-colored spots, the blood, and the bile. The bacillus typhosus is demonstrable in the stools (in about 50 per cent. of the cases), the urine (Wright and Semple), the sputa, the vomita, milk, and the sweat. The bacillus typhosus is most abundant in the duodenum and jejunum; it is practically constant in cultures made from the mucosa of the stomach (Jürgens). Less commonly it has been found in foci of suppuration and in exudations (pleural, endocardial).

The Bacilli Outside the Body.—The bacilli cannot maintain a permanent existence outside the human body. From time to time, however, the conditions indispensable to the growth and development of the typhoid germs prevail, and corresponding with such periods of time more or less extensive epidemic outbreaks of the disease may occur. It is known that the typhoid bacilli may retain their vitality for from seven to fourteen days in water, disappearing from the same on account of the presence of saprophytes; but an epidemic or an endemic of typhoid fever implies persistent contamination of the drinking-water. Multiplication of the bacilli may take place in water, in milk (very rapidly), and in the soil, where they preserve their vitality under favorable conditions (for eleven months—Robertson). Freezing does not kill them, as they may

¹ Jour. Amer. Med. Assoc., April 16, 1910.

live in ice for several months (Prudden). They have been discovered in infected water, but they are thoroughly destroyed by boiling.

Predisposing Causes.—(a) **Geographic Location.**—In temperate zones typhoid fever prevails constantly to a greater or less extent, and is the most important infection. It has been shown in recent times to be comparatively common in the tropics (*e. g.*, India) as well as in many cold latitudes (Iceland, Norway). It exhibits an appalling prevalence and fatality in armies in the field. For example, in the Spanish-American war one-fifth of the soldiers in the national encampments suffered from the disease, with 1580 deaths; while in the South African war the British army lost 7991 men from typhoid fever and only 7582 died of wounds.

(b) **Seasons** exert a decided influence upon the frequency of the occurrence of typhoid. According to the statistics of Murchison, Bartlett, Osler, Hirsh, and others, the time of greatest liability to typhoid fever is during the late summer and the early autumn (August, September, and October). The remaining summer and autumn months yield a relatively larger number of cases than the winter and spring: again, in winter more cases are met with than in the spring, which furnishes fewest number of cases. After hot and dry summers typhoid fever is especially apt to be prevalent, and, according to Baumgarten, a relatively large amount of dust in the atmosphere may disseminate the typhoid germs. Epidemics, however, may occur at any season.

(c) **Condition of the "Ground Soil."**—Pettenger and his disciples contend that when the standing water in the soil reaches a high level fewer cases occur, and when it falls to a low level or below the mean height the cases become more numerous. This dictum, however, has not as yet been conclusively proven with reference to many localities. The poisoned foci, may be more effectively drained by the springs and streams, since the latter contain an increased quantity of solid matter when the ground-water is low. Epidemics of typhoid fever, however, occur repeatedly without regard to the condition of the ground-water.

(d) **Age.**—Typhoid fever may occur at any age. It is, however, especially frequent among young, robust individuals between the ages of fifteen and thirty years. Later in life it becomes progressively less frequent, though cases have occurred at or beyond the seventieth year. Young children are not exempt, and cases among them are of rather frequent occurrence, if we except those under one year of age. When contracted late in pregnancy typhoid may be congenital (Freund and Levy). The typhoid bacilli have been successfully cultivated from the fetus, and Mossé and Fraenkel¹ have confirmed the observation that the Widal test can be obtained from the placenta and blood of the fetus.

(e) **Sex** probably does not affect the degree of liability in typhoid.

(f) **Individual Predisposition.**—This may be *acquired* or *inherited*. An instance of *acquired* predisposition is to be noted in the great susceptibility which exists among persons who have recently moved from rural districts to cities. Thus, Louis found "that of 129 cases, 73 had not resided in Paris over ten months, and 102 not over twenty months." Defective ventilation, filth, overcrowding, and imperfect drainage increase susceptibility. There is evidence to show that the disease is on the increase in rural sections. Predisposition to typhoid may also be *inherited*. Most persons, however, enjoy natural immunity from the affection.

¹ *Journ. des Practiciens*, Jan. 28, 1899.

(g) **Intestinal Catarrh.**—Cases of influenza with catarrh of the gastro-intestinal tract may be followed by typhoid fever.

(h) **Nervous Influences.**—Great mental excitement and overwork.

Immunity.—The occurrence of typhoid fever confers an approximate, though not an absolute, immunity against subsequent attacks.

In this connection two questions present themselves for consideration :

(1) **What are the methods of conveyance of the poison into the body ?**

In the first place, isolated cases and epidemics of typhoid fever are alike to be attributed to antecedent cases of the disease, and this fact presupposes that the bacillus of typhoid leaves the body of the sufferer. It does so in the stools, the urine, and occasionally in the vomitus and sputum. Park¹ states that examinations, both in Europe and America, show that fully 2 per cent. of persons who have had typhoid fever are typhoid bacilli carriers. A few of them pass infected urine, but most, infected feces. During the declining and post-febrile stages the urine is probably the most dangerous excretion containing bacilli. Finally, one in every five hundred healthy adults who have never knowingly had typhoid fever is a carrier through contact with infection. It would seem that there are several periods of "effectiveness" and "ineffectiveness" (the latter coinciding with the early months of the year) of typhoid bacilli carriers. The presence of the lodging-house keeper was the only factor common to seven cases reported by Hutchinson.¹ According to the Germans, the most common source of the bacillus is a patient or chronic carrier, the latter causing about 10 per cent. of the cases. Typhoid bacilluria may persist for a long time after apparent recovery. The dejecta and the urine, which are the principal sources of infection, contain the bacillus of Eberth in great numbers, and these may be conveyed to well persons by—

(a) **Infected Drinking-water.**—In most instances the poison is transmitted from those affected with the disease to those in good health through the drinking-water supply. This has been true in many epidemic outbreaks in which the mode of origin has been traced. Wells, storage reservoirs, springs, and rivers may become contaminated and cause an epidemic.

In the spring of 1885 a most deplorable epidemic occurred in Plymouth, Penna., a town of 8000 inhabitants. At first the nature of the affection was not recognized, and before it ceased to appear 1200 persons were affected, with 130 resulting deaths. This epidemic was investigated by Shakespeare and L. H. Taylor, and was found to have arisen from a single case of typhoid occurring in a house on a hill which sloped toward the water-supply of the town. This patient was ill during January, February, and March, while the ground was frozen and covered with snow, upon which the dejecta were thrown. On March 25th there was a considerable rainfall, followed by a sudden thaw, and the water ran at once through the various surface channels into a brook, which in turn emptied into the reservoir. On April 10th other cases of the disease appeared, and those citizens who obtained their water from other sources than the infected reservoir escaped. The recent outbreaks at Maidstone (1897) and at Butler, Pa. (1903), are equally convincing and instructive as regards the causative influence of a contaminated water-supply.

¹ *British Med. Jour.*, London, March 26, 1910.

² *Jour. Amer. Med. Assoc.*, September 19, 1908.

(b) **Infected milk** frequently conveys the poison. It may become polluted by water which has been used either to wash the cans or for diluting purposes, or the bacilli may be transferred to milk by the unclean hands of the milker. Numerous instructive epidemics, originating in infected milk, have been reported. The occurrence of numerous cases among children suggests contaminated milk.

Solid forms of food (salads, celery, fruits) may be contaminated by infected water or dust or by the fingers of the nurse or the patient. During the late Spanish-American war the typhoid bacilli may have been conveyed from the latrines directly to the victims or to the kitchens and mess-tables by swarms of flies. Vaughan¹ confirms this view, and has also observed that "officers whose mess-tents were protected by means of screens suffered proportionately less from typhoid fever than did those whose tents were not so protected." He believes that fecal matter containing the typhoid germ may adhere to the fly, and be mechanically transported, and further suggests the possibility of the bacilli being carried in the digestive organs of the fly, and deposited with its excrement. H. W. Conn has shown that oysters while being fattened or freshened may become infected with water polluted by sewage, and Foote has shown that the typhoid bacillus will not only retain its vitality in the salt water in which the oysters are fed, but that it will live even longer in the oyster itself. Phillip Marvel has reported a small epidemic (comprising a total of 72 cases) due to infected oysters that occurred at Atlantic City during the months of August, September, and October of 1902. Newsholme² attributed one-third of a total of 56 cases of typhoid to the eating of raw shell-fish.

(c) **Contagion or Direct Transmission.**—This necessitates direct contact with the typhoid stools. It affords a ready explanation for contraction of the disease by internes and nurses who attend to the stools, the bed- and the body-linen of the patient, and by laundresses, who are affected with great relative frequency. Out of 1500 cases treated in the Johns Hopkins Hospital, 31 were contracted in this manner (Futcher).

(d) **"Ground-soil."**—According to Pettenkofer's view, the typhoid poison which leaves the body of an infected person must undergo modification or development in the ground-soil before it is potent to cause the disease in question. The former great prevalence of typhoid fever in Munich was due to the great pollution of the soil (Childs).

(e) **Sewer-gas.**—The recent researches of Bergey and of Abbott show that sewer-gas, *per se*, cannot cause typhoid fever.

(f) **Sand-storms.**—Tooth states that sand-storms may contaminate articles of food with the bacillus.

(g) The hands of chronic carriers may be the medium of transference. Courmont³ claims that dogs are typhoid bacilli carriers.

(2) Through what channel or channels does the bacillus enter?

(a) **In the vast majority of the cases the bacilli are swallowed.** In the stomach they meet with the acid gastric secretions, which often destroy them. The alkaline juices of the small intestine, however, furnish every condition necessary for their further growth and development. They penetrate the mucosa and attack primarily the solitary follicles and

¹ *Phila. Med. Jour.*, June 9, 1900.

² *Brit. Med. Jour.*, June 8, 1895.

³ *Bulletin de l'Académie de Médecine*, Paris, June 28, 1910.

Peyer's plaques. Next they invade the mesenteric glands, reaching the circulation, spleen, liver, and other organs a little later.

(b) The possibility that the bacilli may reach the blood-stream through the *respiratory organs* must be conceded; and hence the added possibility that they may set up initiatory lesions either in the tonsils, lungs, or pleura, passing thence into the circulation, must also be granted. Vaughan inclines to the opinion that the bacillus may be inhaled in the infected dust by troops on the march. Complete desiccation, however, soon destroys the typhoid germ. Primary localization of great severity may also occur in the kidneys and cerebrospinal meninges, giving rise to special clinical varieties (*vide infra*).

(c) **Typhoid Septicemia.**—By this is meant a general infection with the bacilli without localized lesions. The special mode of infection is not clear. Brion and Kayser¹ conclude from extensive bacteriologic and clinical studies that typhoid fever may start as a lymph-and-blood affection (possibly entering by way of the tonsils).

(d) Typhoid infection predisposes the system to secondary infections with various bacilli (streptococcus, staphylococcus, bacillus coli commune, pneumococcus). The portals of entrance for these micro-organisms are various (*e. g.*, respiratory tract; lymphatics).

Clinical History.—I. Incubation.—The average duration of the period of incubation, or the time between the introduction of the poison into the system and the appearance of the first active symptoms, ranges from ten days to three weeks; this interval may rarely be shorter, although oftener it is somewhat longer. During this period the patient may experience no deviation from health, but in most cases there are prodromal symptoms, such as languor, loss of appetite, nausea, headache, neuro-muscular pains in the back and limbs, a disinclination to exercise, etc. These symptoms last from a few days to a week or more.

II. General Symptomatology and Course.—On account of the peculiar temperature-curve in typhoid fever its course falls naturally into three periods—the stage of development; the acme or fastigium (corresponding to the height of the disease); and the stage of decline or defervescence. It is convenient to speak of the various weeks of the affection when referring to these stages. Thus, the first week represents the stage of development (*stadium incrementi*), the second and third weeks (in cases of average severity) the fastigium, while the fourth week in the typical form (the third week in mild cases) corresponds to the third stage (*stadium decrementi*) of the disease.

(a) **Stage of Development.**—The invasion, as a rule, is gradual, the symptoms being chilliness and feverishness, with increase in the severity of the prodromal symptoms. Typhoid fever rarely starts in with a distinct *rigor*. At or about this time nose-bleed may betray the nature of the disease. The symptoms just described are quickly followed by a prostration sufficiently well marked to compel most patients to take to their beds. From this latter event is usually dated the *onset* of the affection. It is safer, however, to regard the time of occurrence of the above-mentioned symptoms (elevation of temperature, with its attendant discomforts) as the time of onset, since many patients continue in their avocations for days after the first symptoms appear. The *onset* may be

¹ *Deutsches Archiv f. klin. Medicin*, last indexed, vol. xlv., p. 1832.

marked by symptoms resembling influenza (Bunce). In my experience cases in which general pains, including backache or slight pharyngitis, are seen at the onset are not rare. Again, invasion may be ushered in by various nervous symptoms (*e. g.*, convulsions, in children) or marked pulmonary features, especially those of severe bronchitis.

With the progress of the initial period the symptoms usually increase in severity; the *fever* rises day by day, terrace-like, till, at the end of four or five days, the second stage, or fastigium, is reached. Anorexia, thirst, and headache are often marked, the skin hot and dry to the feel, the tongue coated, the sleep disturbed, and constipation is generally present. The patient may complain of sensations of chilliness alternating with flushings of heat, and there is a slight cough. The *pulse* is somewhat quickened (from 90 to 110 per minute) and is full.

The *physical signs* are not prominent. The abdomen is often slightly distended and tender; the spleen is found to be swollen. The association of splenic enlargement and dry bronchitis point to this disease.

(b) **Fastigium**, or the **second stage**, commences on the fourth or fifth day, and lasts, in typical cases, about two weeks. During the first week of the fastigium (the second of the disease) the general symptoms become more marked. The *fever* remains high, the evening temperature usually reaching 103° or 104° F. (40° C.), and exhibits the continued type. The *pulse* is accelerated, but not dicrotic. The headache disappears, and mental dulness and slowness are conspicuous, but there may be mild delirium, particularly at night. There is a dry *cough* and the physical signs indicate more or less extensive bronchitis. The *tongue* is coated and may become dry, the belly is somewhat swollen and tender, and diarrhea replaces constipation. The *spleen* is decidedly enlarged, and about the eighth day of the disease a number of roseate spots appear on the trunk. During the latter part of this week a grave or even fatal condition may be developed as a result of intense nervous or pulmonary symptoms, intestinal hemorrhage, or perforation.

During the second week of the fastigium (the third week of the disease) the marked general symptoms already noted persist in severe types of the affection. The *pulse* varies from 110 to 130, and is now often dicrotic, while the temperature may approach the remittent type. In addition this period furnishes most of the untoward *complications* (lobular pneumonia, hypostatic congestion of the lungs, intestinal hemorrhage, perforation, peritonitis), and in the absence of serious local complications grave general conditions may be presented. The duration of this stage varies with the severity of the type.

(c) **Stage of Decline or Defervescence**.—At the end of the second stage, and about the twenty-first day of the disease, in favorable cases the *fever* begins to decline, and with it the other general and local symptoms gradually disappear. This is followed by true convalescence. In protracted cases, however, the fourth week of the disease may present much the same clinical indications as the third, and these may even be intensified. Frequently an aggravated type of the *typhoid state* is now superadded, the symptoms being stupor, muttering delirium, subsultus tendinum, a rapid, feeble pulse, a dry, brown tongue, marked diarrhea, greatly swollen belly, and an involuntary discharge of feces and urine. Inflammatory complications may add to the perils of the condition.

In not a few cases the febrile period is prolonged into the fifth, and

rarely into the sixth or even the seventh week, and the fever observed when defervescence is retarded presents an irregular type. I have elsewhere reported a case in which it lasted not less than seven weeks.¹ About this time recrudescences and relapses may occur in typical cases. Different epidemics of typhoid fever, however, vary so greatly in their clinical characteristics as to make it impossible to include all cases in any outline of the course of the disease that might be attempted.

III. Chief Clinical Features in Detail.—(a) **Course of the Fever.**—During the stage of development (the first four or five days) the temperature usually rises in “step-ladder” fashion. The evening exacerbation is on each day from a degree and a half to two degrees higher than on the preceding, and the same is true of the morning remissions. A glance at the temperature-charts (Figs. 2 and 3) will show that the morning remissions touch a level from one-half to one degree lower than the preceding evening registers. This stage is rarely met.

When the fastigium is reached, the evening temperature may be 103°, 104°, or 105° F. (39.4°–40.5° C.), and is usually thus maintained, with the slight morning remissions. The tide-like character of fever-curve seen in the initial period is absent. Often, during the latter half of the fastigium (the third or fourth week of the disease) the morning fall of temperature becomes decidedly greater. According to my own observation, the height of the fastigium is reached a day or two after its onset or at the end of the first week of the affection. Marked morning remissions are a favorable indication. On the other hand, and contrary to the general rule, the morning temperature may be higher than the evening, forming a somewhat unfavorable symptom. Morning temperatures of 104° F. (40° C.) or over are indicative of a serious type. In many instances of mild grade the evening temperature at no time exceeds 103° (39.4° C.), but oscillates between 100 $\frac{3}{5}$ ° and 102 $\frac{3}{5}$ ° F. (38.1°–39.2° C.). In cases of average intensity the morning remissions touch 102°–102 $\frac{3}{5}$ ° F. (39.2° C.), and the evening exacerbations reach 104–104 $\frac{3}{5}$ ° F. (40.3° C.). When the temperature rises above 105° F. (40.5° C.) hyperpyrexia exists. Ampugnani made studies of hourly charts from 200 cases of typhoid fever, and found the maximum temperature to occur between three and six o'clock in the afternoon, and the minimum between four and eight o'clock in the morning. The duration of the fastigium exhibits a wide range and is dependent upon a variety of conditions—*e. g.* the degree of mildness or severity of the type, the presence or absence of complications, etc. In cases of a mild character it lasts from a few days to one week; in cases of average severity, from ten days to two weeks; in the severest forms, from two to four weeks.

In typical cases the end of the fastigium marks the beginning of the last stage (that of defervescence), and during this period the temperature falls by *lysis*. Measured by days, it declines by degrees, both the morning and evening temperatures being often one or two degrees lower than on the preceding day. Thus is formed a more or less regular step-like line of descent. To this general rule there are two notable exceptions: From the beginning of the period of defervescence the morning remissions may strike the normal point, while the evening ex-

¹ “A Case of Typhoid Fever; numerous Intestinal Hemorrhages, the Amount of Blood Lost being Seventy-eight and one-half Ounces; and Obstinate Vomiting, with Recovery,” *International Clinics*, vol. i. 5th series, April, 1895, p. 29.

Fig. 2.—Typical typhoid curve.

Fig. 3.—Curve in severe typhoid.

acerbations become less and less marked, until they also touch the normal. Under these circumstances the temperature-curve resembles somewhat that of the quotidian intermittents, and rarely the tertian fever-curve obtains. In comparatively rare instances the morning temperature shows a deeper remission on each successive day, while the evening temperature remains high for several days, when it also declines. This period lasts from one week to ten days—a longer time than the initial stage with its ascending type of fever.

In the severe and protracted forms of typhoid fever there occurs between the second stage (*fastigium*) and the third stage (*defervescence*) another, to which Wunderlich has given the name of the “ambiguous period.” This lasts from a few days to a week or more, and is characterized by a striking diurnal range of temperature, with marked irregularities. It is probable that it is sometimes produced by an auto-intoxication.

Abnormal Course of the Fever.—The pyrexial peculiarities yet to be pointed out are less usual than the foregoing, although of sufficient frequency of occurrence to demand a brief description.

The first stage varies but little from the regular course described above. A sudden elevation of temperature, however, is seen in those cases that begin with a severe rigor, accompanied by pneumonic, catarrhal, and gastro-intestinal symptoms. Pepper and Stengel have reported seven cases* with acute onset, and Moore, of Dublin, states that the whole course (since 1889) has become more typhus-like than formerly.

In the lightest forms the *fastigium* may be practically absent, *defervescence* setting in upon the first day of the *fastigium*. There is also a class of cases in which, throughout the greater part of their course, the fever is distinctly intermittent or remittent, and in which careful blood-examination fails to disclose the *plasmodium malarie*. The same form of temperature-curve is seen in those rare instances of typhoid fever which occur in subjects previously infected with malaria. These two classes of cases run a favorable course as a rule.

Sudden deep temporary drops in the temperature may occur during the *fastigium*. (1) This may take place during the early part of the *fastigium* without obvious cause. (2) Intestinal hemorrhage almost invariably produces a sudden, and sometimes a great, fall of temperature. Osler has reported a case in which a drop of 10° F. (5.5° C.) followed *melena*. The blood does not appear in the evacuations of the patient for six to twelve hours or more after the temperature has begun to fall; and hence a critical decline of temperature during the latter part of the second and the third week of the disease suggests that hemorrhage has probably taken place. (3) The occurrence of *peritonitis* is marked by a sudden and considerable fall of temperature. (4) In the female, abortion or premature delivery occurring in the course of typhoid fever produces a decided lowering of the temperature. (5) Collapse of the circulation sometimes occurs with a notable remission of temperature—an ominous association of events, and one which I observed in two cases occurring in females in the Medico-Chirurgical Hospital. In one of these cases two such periods of collapse occurred, and in the other three, though both finally recovered under prompt and continuous stimulation. Occasionally *hyperpyrexia* is observed in typhoid

fever, and most frequently just before dissolution, when the thermometer may register 108° or even 109° F. (42.7° C.). A fresh rise with marked irregularity of temperature may occur during the latter part of the fastigium or the period of decline, and is often dependent upon some local complication (late pneumonia, parotitis, etc.).

The stage of defervescence is sometimes much prolonged, though most frequently there is simply a slight evening elevation (99° to 100° F.—37.7° C.), the morning temperature being normal. The causes of retarded decline are, for the most part, obscure. I believe that many of them are ascribable to a mild grade of auto-intoxication, and in my hands a mild saline laxative has been the means of cutting them short in a number of instances. An examination should, however, be made for some localized inflammatory complication, though this is not always discernible, as in the case of suppuration in the mesenteric glands. Slug-gish typhoid ulcers, which refuse to heal promptly, may act as a cause of the slow decline; they are often due to the post-typhoid anemia and exhaustion.

Post-typhoid Elevations of Temperature.—After both the evening and morning temperatures have become normal, fresh temporary elevations (102° or 103° F.—38.8° or 39.4° C.) frequently appear. They are, as a rule, unassociated with any other symptoms, and at the end of a few days the temperature falls rapidly to the normal. These are termed *recrudescences*, and are to be distinguished from true typhoid relapses. They are probably produced in various ways—by errors in diet, constipation, mental emotion, excitement. “There are cases in which the presence of the fever seems to be really a nervous phenomenon” (Osler). It is most common in children and in persons of a decidedly nervous temperament. Certain local sequelæ may cause post-typhoid fever, such as abscess and periostitis. Rarely during convalescence a sudden and marked elevation of temperature, accompanied or not by rigor, occurs, but it is usually of short duration and seldom is of serious import. I saw, with the attending physician, Dr. Modell, a case in which the temperature had been normal for six days, when rigors, followed by steep elevations of temperature, occurred several times and at intervals of thirty-six or forty-eight hours. These high temperatures were followed by a rapid decline to the normal and by sweating, leaving the patient profoundly exhausted. Subsequently the convalescence was slow, but uninterrupted.

Afebrile Typhoid.—As the term indicates, typhoid fever may run a course attended with all of the characteristic symptoms save only the fever. Cases of this kind are of great rarity.

(b) *Skin.*—The *eruption* is highly characteristic, and usually decides the diagnosis. It makes its appearance on or about the eighth day, and sometimes a little later. Occasionally it does not appear until the tenth or twelfth day of the disease. It consists of distinct, rose-colored, and slightly elevated papules, having a rounded or lenticular form and a diameter varying from one or two to three lines. The papules are almost invariably found upon the trunk, and especially upon the upper part of the abdomen and the lower part of the thorax, to which regions they may be wholly confined. They may, however, be absent from the usual seats and present elsewhere, so that the sides of the trunk, the

back, and the thighs should always be inspected. They disappear upon pressure, but reappear when the pressure is removed. These rose-colored spots last three or four days, and appear in successive crops, each one being made up, usually, of a few spots—a half-dozen to a dozen. Rarely the eruption is abundant on the trunk, even extending to the extremities and head; but there is no direct correspondence between the extent of the eruption and the severity of the cases. Occasionally the spots are entirely absent—a condition most frequently met with in children, and less often in elderly persons.

Other eruptions are often present, and their negative diagnostic value must be kept in remembrance. Minute pearly vesicles (*sudamina*) may appear. They are limited to the abdomen, the axilla, and to the inner surface of the thighs as a rule, and are in great measure due to profuse sweating.

A scarlet-colored *erythematous eruption* sometimes appears at a comparatively early period in typhoid fever. *Urticaria* and *purpura* are rarely seen. Out of 250 cases of typhoid fever among the soldiers in the Spanish-American war treated in the Medico-Chirurgical Hospital two manifested purpuric spots. *Extensive ecchymoses* may occur, but are rare, and merely symptomatic of the hemorrhagic diathesis. Cutaneous *boils* and *abscesses* due to secondary infection with the pyogenic cocci are a comparatively frequent and late development in the course of the disease. *Pelionata typhosa* in the form of little bluish subcuticular spots (the “*tâches bleuâtres*” of the French writers) may appear; but they are not related specially to typhoid fever, and in a recent case of my own were undoubtedly due to pediculi. *Gangrene*, chiefly of the lower extremities, has been noted in 214 cases (Keen), and is due to the diffusion of the bacilli and their toxic products, to an obliterating endarteritis, thrombosis, or embolism.

Profuse sweats form a conspicuous symptom in many epidemics of the disease, with or without accompanying fits of chilliness or rigors, and constitute the sudoral form of typhoid fever (Jaccoud). Some of these cases resemble ordinary intermittents. *Edema* of the skin may be observed and is due most frequently to anemia or cachexia, though sometimes to nephritis. A local form of edema affecting the leg is not uncommon, and for this form thrombosis of the femoral vein is chiefly responsible. A peculiar “musty” odor is exhaled from the skin in some instances of typhoid fever. The patient assumes the dorsal decubitus and is exposed, particularly in cases of prolonged duration, to the danger of the formation of *bedsores*. They are most prone to occur on the nates and the heels, and, once started, they are apt to spread till they attain to large dimensions, with extensive undermining of the skin. The condition is now serious. During and after the conclusion of convalescence the hair falls out, but, fortunately, it is invariably renewed. The *nails* sometimes become roughened and brittle, while transverse pale lines or ridges can usually be observed in them, marking the impairment of nutrition during the disease (*vide* Relapse). *Jaundice*, due to a variety of causes, is a rare symptom, and generally does not come on until the middle of, or until late in, the disease (Da Costa).

(c) **Digestive System.**—The symptoms referable to the gastro-intestinal canal, though not very striking in most cases, are of the utmost

importance and interest because of their direct connection with the pathognomonic lesions of typhoid. Beginning with the intestinal canal, and thence proceeding to the symptoms presented by the stomach, spleen, liver, throat, and mouth, will be a natural and convenient order.

At the onset of typhoid fever *constipation* is the general rule, and this may persist to the end of the illness, though more commonly a moderate diarrhea appears. Osler¹ in the Johns Hopkins Hospital, however, met an initial diarrhea in 322 out of 829 cases. During the second week of the affection the stools number, on the average, from two to four or more daily. It is only in comparatively rare instances that ten or more movements per diem occur, and the severity of the diarrhea depends largely upon the degree of catarrh, particularly of the large intestine. When, however, the ulcerative process is chiefly limited to the colon, it is an important factor in the production of the diarrhea. Indeed, in those instances—not altogether rare—in which there is urgent diarrhea of a *dysenteric character*, the ulcers are especially marked in the colon, with diphtheritic inflammation of the surrounding mucosa. Involuntary discharge of the feces may occur.

The *stools* present a characteristic yellow appearance, suggesting by their color and consistence a comparison with pea soup. They are usually either fluid or of the consistence of jelly, and are offensive and of an alkaline reaction. On standing they separate into two layers—an upper, liquid, cloudy layer, and a lower, thick yellow, sedimentary layer, in which, on macroscopic examination, remnants of food and grayish yellow fragments (necrotic crusts of Peyer's plaques) from a half to an inch in length may be detected. Microscopically, they have been found to contain undigested particles of food, epithelial debris, blood-corpuscles, crystals of triple phosphates in abundance, and innumerable bacteria. Laboratory experimentalists are able to demonstrate the presence of the typhoid bacillus in the dejecta. *Tympanites*, mainly affecting the colon, is a common though rarely a striking feature, and cases of a quite serious nature are observed in which the abdomen presents a concavity throughout the entire illness. The latter is less unfavorable, by far, as a symptom than excessive tympanites, which interferes with both the respiration and heart action. Tympanites is apt to be most marked in serious cases which have diarrhea as a prominent symptom, though the latter may not even be present. It is due to the generation of gas from decomposing food, and to the arrest of peristaltic movements in consequence of degeneration of the muscularis of the intestines. *Pain* is absent in the majority of cases, and when present is not intense, save in rare instances. Pressure upon the ileocecal region usually causes a *gurgling noise*, but, although this symptom is commonly present, it is not characteristic of the disease. There is generally also a slight degree of tenderness of the abdomen under pressure, most marked in the right iliac fossa, and hence, in all probability, due to the presence of ulcers in this region. Absence of tenderness, however, is not a safe indication of the absence of extensive ulceration. *Extreme sensitiveness* generally denotes peritonitis (often without perforation), although the symptom may be marked in constipation.

Intestinal hemorrhage occurs in from 4 to 7 per cent. of cases, its

¹ *Philada. Med. Journ.*, October 15, 1900.

frequency varying with different epidemics. The hemorrhages appear almost invariably during the latter part of the second and third week, being caused by the opening of blood-vessels during the necrotic or ulcerative process. The amount may be small, or it may be from 1 to 2 or 3 pints (0.5–1.5 liters), or even more. In one of my own cases the total amount of blood discharged from the bowel was nearly 5 pints (2.5 liters), and yet the patient recovered. The blood presents a dark hue, and that which is passed last may be tarry. Roman has examined the feces in 50 cases of typhoid fever with a view to the detection of occult bleeding. Blood was found in 14 cases, and of these, 7 were severe, 3 moderately severe, and 4 slight.

The significance of intestinal hemorrhage is always grave. On the other hand, recovery is possible even if the hemorrhage be copious and oft-repeated; and in general terms it may be said that death supervenes in from 30 to 40 per cent. of all cases. R. G. Curtin has recorded 60 cases, of which 46.6 per cent. died; he argues that cold applications to the skin and the necessary disturbance in giving a cold bath tend to produce melena. It occurred in more than the usual proportion of cases under my care during the Spanish-American War, probably owing to the fact that the men were conveyed from the various distant camps to the hospital. A fatal result may occur as the direct effect of a profuse hemorrhage. When death does not follow immediately, the signs of collapse and of anemia appear; yet intestinal hemorrhage sometimes exerts a favorable influence, stupor and delirium quickly giving place to consciousness. When typhoid fever occurs in the hemorrhagic diathesis, hemorrhage occurs from various outlets.

Perforation, which almost invariably produces fatal diffuse peritonitis, is the accident most to be dreaded. It does not bear a fixed relation to the severity of the affection. In the 2000 Munich cases (*vide supra*) perforation occurred in 114; and, according to Fitz, who tabulated 4680 cases of typhoid fever, there is a mortality of 6.58 per cent. from perforation of the bowel. Scott's statistics, embracing 9713 cases from English, Canadian, and American hospitals, give a mortality of 3.6 per cent. from perforation. It is much more common in males than in females, and appears in a ratio of about 71 to 29. *Age* has a decided influence, the complication occurring oftenest between ten and forty years of age, while in children it is rare. It may occur at any time in the course of typhoid fever, but it is most common between the second and fourth weeks of the disease. In the cases analyzed by Fitz perforation was found in the ileum in 81.4 per cent., in the large intestine in 12.9 per cent., in the vermiform appendix in 2.5 per cent., and in the jejunum in 1.29 per cent. The accession of hypertension of the pulse is indicative of approaching perforation. The accident is usually announced by the sudden advent of acute *pain* in the abdomen, quickly followed by the symptoms of *collapse*; and the fact that diffuse peritonitis, following perforation, may develop insidiously must be recollected. The abdominal muscles become rigid, sensitive to touch, and later tympanites develops. Fluctuation can sometimes be elicited. On *percussion* splenic and hepatic dullness is often absent, but hepatic dullness is also wanting when the distended intestines lie in front of the liver. The collapse of the circulatory system is evidenced by the

pinched features, hollow cheeks, vomiting, and the small, frequent pulse. Leukocytosis is a valuable diagnostic symptom. Crile found a rise in the blood-pressure in five cases. Wilson has emphasized the importance of an early diagnosis and of immediate resort to operative intervention.

The instances that develop independently of actual perforation usually assume the local or circumscribed form of peritonitis; they are occasioned in various ways—*e. g.*, by direct extension of the inflammatory process from the intestinal ulcers, primary localization of the virus in the peritoneum, and rupture of the mesenteric glands. The condition presents corresponding areas of tenderness under gentle, and especially under prolonged, pressure. It is, however, confessedly difficult to diagnose between certain intra- and extra-intestinal states. Generalized peritonitis may succeed the circumscribed variety.

The *mesenteric lymph-glands* may soften or suppurate (*vide Pathology*), and, as before mentioned, may be the exciting cause of a recrudescence, or they may rupture and cause diffuse peritonitis.

The Spleen.—With few exceptions the spleen is enlarged in typhoid fever, the edge usually being palpable below the margin of the ribs, on or before the commencement of the fastigium. It generally goes on increasing in size till near the beginning of the third week, and lessens during the latter part of the third and fourth weeks. Swelling of the spleen is sometimes absent after a copious intestinal hemorrhage and in elderly typhoid subjects. When the tympanites is excessive, we can in most cases satisfy ourselves of its existence or non-existence by careful palpation. Suppurative infarcts or softening of the spleen may start a peritonitis. Rarely spontaneous *rupture* of the organ may occur, which is manifested by intense pain in the splenic region. Bryan reports a case and has collected 24 others from the literature.

The Liver.—A slight swelling of the *liver* can sometimes be detected. Among the least frequent complications is *jaundice* (*vide supra*); it may be due to cholangitis, to abscess, and to gall-stones. *Cholecystitis* caused by the typhoid bacillus (*vide Pathology*) may arise during the attack or long after complete recovery. In most cases the lesions are catarrhal, but they may be suppurative, in which event perforation followed by peritonitis may occur. *Calculous cholecystitis* is frequently caused by the typhoid bacilli, but may not manifest itself for a variable number of years. *Suppurative pylephlebitis*, secondary to perforative appendicitis, may be a complication. Multiple abscess may occur.

The Stomach.—The stomach presents no characteristic symptoms. Of the *anorexia* enough has been said, but during convalescence the appetite returns, becoming even voracious. *Nausea* and *vomiting* may occur during any stage of the disease, but are most common at the beginning. When they appear as late symptoms they are probably excited either by a typhoid ulcer or by peritonitis. Nausea is often traceable to other causes—*e. g.*, to errors in diet, or to the use of irritating medicaments, but vomiting also occurs from unknown and inevitable causes. It may become a serious or even fatal symptom. Hiccough is a rare but serious symptom. Hematemesis has been observed, although practically unknown.

The Pharynx.—The pharynx frequently shows *catarrhal irritation*, and the patient may complain of dryness or a burning sensation in the

throat. Actual *sore throat* may be present at the time of onset, associated with a diffuse *erythematous rash*, suggesting scarlatina.

The Tonsils.—There is a special form of typhoid—*tonsillo-typhoid* or *pharyngo-typhoid*—in which there appear upon the tonsils peculiar patchy elevations, whitish in color, which undergo subsequent ulceration. It is not improbable that these lesions result from the local action of the specific bacillus in an unusual situation. *Thrush*, affecting the mouth, throat, and even extending to the esophagus, not infrequently arises as a complication. The *tongue* is heavily coated, as a rule, with a yellowish-white fur; later it clears off near the edges and tip, while the center becomes dry or brown and sometimes fissured. The lips are also dry, sometimes fissured, and often covered with dry, black crusts (*sordes*). *Ulcerative stomatitis* may occur if the mouth be not kept clean. Under these circumstances secondary lesions evincing unpleasant and even serious symptoms may also arise in organs more or less remote from the mouth, and among these is *parotitis*, which is most probably caused by the staphylococcus or streptococcus reaching the parotid gland by way of Steno's duct. The condition is betrayed by such symptoms as pain, redness, and finally by fluctuation, with an elevation of the bodily temperature. It is a late-appearing development, and is usually unilateral, though it may be bilateral. *Suppurative otitis media*, a rarer complication, arises in a similar manner, the pathogenetic agents reaching the ear through the Eustachian tube.

(d) **Respiratory System**.—As pointed out in the section on Pathology, *bronchitis* is almost invariably present, but in the majority of instances the cough is slight. The condition is recognized by the existence of numerous sibilant râles. Very rarely is it a striking feature in the early stage of typhoid fever, and then, except this fact be remembered, room for error of diagnosis exists. Moreover, in cases that are improperly treated the bronchial secretions are apt to accumulate, and a well-marked bronchitis may be the result. It may be said, however, that, as a rule, bronchitis does not assume a severe type in cases which receive proper attention from the beginning, provided the patient be not unusually stupid or unconscious. When the nervous phenomena are pronounced, and the patient maintains the dorsal decubitus (expectorating little or nothing), bronchitis of a severe grade and affecting the smaller bronchi is almost inevitable. The occurrence of an intense generalized bronchitis is also favored by certain other conditions, such as corpulence, advanced age, and emphysema. These cases are apt to lead to lobular infiltration—*aspiration-pneumonia*.

Lobular pneumonia may take on a putrid nature and the consolidated area may become *gangrenous*. As a sequel, *pleurisy* with effusion or *empyema* may originate in consequence of the infiltrated lobules being contiguous to the pleura. If the lobules occupying the periphery of the lung become gangrenous, perforation of the pleura, leading to *pyopneumothorax*, may result. As pointed out by Gordinier and Lartigau,¹ in the majority of instances of typhoid pleurisies the aspirated fluid has been found to be purulent in character. Lobular pneumonia may be attended with *hurried breathing* or troublesome *cough*.

¹ *Amer. Journ. Med. Sci.*, January, 1901.

More commonly, the *local symptoms* are in abeyance, and this is especially true of the severer cases which are attended with profound nervous prostration and more or less unconsciousness. Sole reliance is to be placed upon the results of a *physical examination*, which should be repeated daily. Points or surfaces of dulness, near the bases of the lungs, are found on percussion. Fine moist râles, heard in every direction, and especially marked toward the bottom of the thorax, form a characteristic sign. A certain diagnosis of lobular pneumonia demands the combined presence of both the circumscribed dulness and moist râles.

Lobar pneumonia is a not uncommon complication. In a small percentage of cases it develops early, and is most probably the result of a special concentration of the poison in the lungs, giving rise to the so-called *pneumo-typhoid fever* (*vide infra*, Varieties). These cases are often mistaken for primary lobar pneumonia. Their onset may or may not be marked by a rigor, but it is usually more gradual than that of primary lobar pneumonia. At the end of the first week or thereabouts the pulmonary symptoms gradually abate, while those characteristic of typhoid (enlarged spleen, roseate spots, etc.) come to the fore. Wagner, Leichtenstein, and Aufrecht entertain grave doubts as to the existence of a pneumo-typhoid. I have, however, had under my care a case in the Medico-Chirurgical Hospital that was proven by the Widal reaction. Lobar pneumonia more often develops as a late complication—in the second or third week, or even during convalescence—but it is not attended by the usual phenomena (rigor, cough, rusty expectoration, intense chest-pain), and hence may be easily overlooked. The temperature may be either quite elevated or at times only moderately so. Lobar pneumonia, the complication, is principally due to the pneumococcus. The *diagnosis* is to be made from the physical signs, together with the peculiar temperature-curve, which may present marked irregularities. Pulmonary infarction and abscess of the lungs are occasional complications.

Hypostatic congestion of the lungs, due to enfeeblement of the cardio-pulmonary circulation, is a frequent concomitant, appearing in the third week of the disease. It is generally bilateral, and is promoted by the effects of gravitation. It is almost always associated with more or less edema of the lungs. The subjective symptoms, including fever, are usually negative, while the objective signs are those of partial or complete consolidation of the bases (defective resonance or dulness, bronchovesicular breathing, with moist râles). *Miliary tuberculosis* rarely develops as either a complicating affection or, it may be, as a sequel. Of 249 autopsies in fatal cases of typhoid fever only four showed acute tuberculosis to have been associated.¹

Laryngitis, indicated by hoarseness, is an occasional complication. The laryngeal ulcers may extend in depth to the perichondrium, and promote that grave condition, *perichondritis*, leading to necrosis of the cartilages with edema of the glottis and stenosis. A third form of laryngeal complication is that in which the muscles are deprived of their function because of paralysis (Gibb).

Epistaxis appears early in some cases and is a valuable diagnostic symptom. It may also occur during the fastigium, particularly toward

¹ "The Relation of Typhoid Fever to Acute Tuberculosis," *Amer. Jour. Med. Sciences*, May 4, 1904, by the writer.

its close, when it is of no diagnostic, but of grave prognostic, significance. In a case I saw with the late Dr. Snively it led to a fatal issue.

(e) **The circulatory system** presents no characteristic symptoms. The *heart-sounds* are but little affected, as a rule. In cases of asthenic type and in severe typical instances the first sound of the heart may grow quite feeble and ultimately resemble the second (embryocardia). Under these circumstances a soft systolic murmur may be faintly heard along the left border of the sternum. Among occasional *complications* presented by the heart is pericarditis, and still less frequent is endocarditis. Myocarditis is more common. The sudden development of circulatory collapse in the course of typhoid fever, as previously noted, may be due chiefly to myocardial inflammation; and there may be a brief though alarming derangement of the heart action, due to functional disturbances.

The *pulse* is accelerated, but not, as a general rule, in proportion to the height of the temperature until late in the affection. Its average rate is from 84 to 108. The temperature, moreover, may be of average height, while the pulse is normal or only slightly quickened throughout; and hence the increase in the pulse-rate cannot be due solely to the elevation of temperature. As before intimated, the extreme debility which comes on during the third week in severe cases may have, as one of its manifestations, a very rapid pulse, reaching to 160 or more (the so-called running pulse), and with or without marked irregularity. Slight *irregularity* is sometimes observed, either during the height or decline of the affection, but as a rule proves of no serious consequence. Marked temporary accelerations are often caused by undue exertion or mental excitement. The lowered arterial tension is shown by a dicrotism of the pulse—a non-characteristic symptom, however, since it is well marked in other acute infectious diseases, although less commonly. During convalescence the pulse often becomes abnormally slow (*brachycardia*). *Per contra*, less commonly, the pulse-rate is increased during convalescence. I have found the systolic arterial pressure during the fastigium to range from 110 to 125 mm. Hg. (Riva-Rocci instrument); it declines further late in the disease. The fall in the diastolic pressure is proportional. During convalescence the blood-pressure again rises, reaching the normal in from two to four weeks.

Venous thrombosis occurs in 1 per cent. of all cases (Murchison). Its most frequent seat is the left femoral, and the next most frequent the right femoral vein, and it is the immediate result of cardiac weakness, except perhaps in those rare instances that arise early in typhoid. In most cases there is, doubtless, more or less phlebitis, and the bacilli have been found in the thrombus. The condition may be bilateral. Coming on, as it usually does, during convalescence, it manifests itself by swelling and edema of the extremity affected. There are *pain* in the thighs and calves, and tenderness over the course of the vein, and often over the calf of the leg as well. It causes *fever* of a moderate grade and irregular type. In the course of from two to three weeks the swollen member may be reduced to its normal dimensions. This complication is usually not serious, but occasionally clotting extends into the pelvic veins, and into the vena cava, thence even into the right auricle, inducing fatal syncope, and sudden death has resulted from the detachment of emboli.

The thrombus may undergo suppuration, leading to systemic septic infection.

Thrombosis and *embolism* in the arteries, with renal, splenic, and pulmonary infarcts, may be encountered in typhoid fever.

The large or small arteries may become obliterated, either by embolism or thrombosis, in extremely rare instances, but whether the thrombosis under these circumstances is brought about by a peculiar condition of the blood which favors clotting, or by a localized arteritis, is not definitely known. If, as is usual, the femoral artery be involved, the blood-supply to the foot and leg is cut off and *gangrene* of those parts must follow. The condition may be bilateral. It may be detected

FIG. 4.—Chart illustrating the blood-changes in typhoid fever: upper curve, red corpuscles; middle curve, hemoglobin; lower curve, white corpuscles.

early, owing to the absence of a femoral pulse, before the signs of gangrene appear. The condition is highly dangerous.

The *blood* presents certain changes, some of which are valuable for diagnostic purposes. The red corpuscles may be relatively increased in number during the febrile period, owing to loss of water (*e. g.*, profuse sweats, diarrhea). There is, in most instances, little or no decrease in the number of red corpuscles till the end of the second week. They are markedly diminished, as a rule, during convalescence, the oligocythemia bearing a close relation to the severity of the disease.

There is a greater relative decrease in the amount of hemoglobin than in the number of red corpuscles. The number of white corpuscles remains at or a little below the health standard until late convalescence, when it sinks to a moderate degree—furnishing a count of about 2000 per c.mm. (*leukopenia*). This fact is an important aid in the differentiation of uncomplicated typhoid fever from leukocytotic affections. Leuko-

cytosis, however, occurs in typhoid, with hemorrhage and perforation, and especially in connection with "large abscesses, phlebitis, peritonitis, pneumonia, pleurisy, periostitis, cystitis, and cholecystitis" (Thayer). Transient leukocytosis occurs after cold baths. Naegeli¹ found an early neutrophilic leukocytosis of moderate degree which rapidly decreases. In the second stage neutrophiles and lymphocytes are still further decreased, the former at last disappearing, while the latter begin to increase again, and so continue until defervescence. During the decline of the fever the neutrophiles reach their minimum, the lymphocytes are greatly increased, and the eosinophile cells gradually return to their normal number. After the disappearance of the fever a lymphocytosis may occur. The blood-characters in typhoid are shown in the accompanying chart (Fig. 4).

(f) **Nervous System.**—The persistent *headache* that is almost always present is among the most prominent symptoms during the first week, but it diminishes steadily during the early part of the second, as a rule. It affects the temporal, occipital, and cervical regions, and when the onset is comparatively sudden, pain in the back is also a more or less conspicuous feature during the first few days of the illness. In a small class of cases, however, the effects of the typhoid bacilli or their toxins are manifested solely in the nervous system from the very onset. In such there are violent headaches, retraction of the head, rigidity, photophobia, and muscular twitchings (rarely convulsions)—all of which symptoms indicate *meningitis*. The diagnosis of meningitis as a complication must be made with extreme caution, since, no matter how complete the clinical picture may be, the post-mortem examination usually reveals a total absence of meningeal inflammation. It must be recollected, however, that the lesions may be wholly microscopic. *Vertigo* may accompany the headache, but it seldom outlasts the latter. Before delirium manifests itself wakefulness and restlessness at night are very annoying, and later the same symptoms may be observed associated with the delirium. In cases of moderate severity *mental dulness*, and even *actual hebetude*, are almost invariably present. Questions are apt to be answered inconsistently and in monosyllables.

Delirium is frequent in the severer cases. It is, however, not an uncommon event for those of moderate severity to be free from this symptom throughout the attack. It is, as a rule, most marked at night or at some time when the patient is left alone. His delusions may impel him to attempt to leave his bed, but more commonly there is *mild* or *noisy delirium*, with more or less restlessness. He may lie somnolent, soliloquizing in a loud whisper (muttering delirium), and this so-called *typhomania* may gradually give place to actual coma toward the close of the middle period of the disease. In not a few cases—mild or severe—*coma* is developed suddenly, and is often a mortal symptom. Still another unfavorable sign is a picking at the bed-clothes or a grasping at imaginary objects (carphologia).

The delirium may assume an hysteric type, the patient usually exhibiting the saddest emotions, and if he be an alcoholic he may be seized with *delirium tremens*. In a case of typhoid fever that I saw with Dr. S. W. Morton hysteric delirium developed during early convalescence, but did not last more than twenty-four or thirty-six hours.

¹ *Deutsche Archiv für klin. Med.*, Band lxxvii., Hefte 3 u. 4.

The *motor nerves* also present notable disturbances in association with the sopor and the forms of delirium previously described. Slight twitchings of the muscles of the face and extremities are quite common, and when they affect the tendons of the wrist and fingers the term *sub-sultus tendinum* is applied. The lips, tongue (especially when protruded), lower jaw, and even the extremities, are often in a state of constant tremor. During this motor irritability the reflexes are increased, but when profound coma comes on they are either largely diminished or totally abolished. The toxins of the typhoid bacillus, acting poisonously upon the nervous centers, are undoubtedly the cause of the nervous symptoms in typhoid.

Nervous complications and sequelæ may arise. Chief among these is *paralysis*, which is most probably due to neuritis. The lesion may involve one, two, or more nerves, and in this way we may have either a paralysis of one limb or, more rarely, a true paraplegia. *Aphasia* may be a sequel, particularly in children. *Hemiplegia*, due to hemorrhage or a localized encephalitis, may occur either as a complication or sequence of the disease. Following typhoid fever, the patient may exhibit evidences of *mental enfeeblement*, and even *insanity* where a predisposition to this condition has existed; and insanity is relatively more common after this disease than after any others belonging to the same class. I have seen four instances, all of which recovered, while Osler has seen five, four of which ended similarly. It is in most cases, as pointed out by Wood, a confusional insanity, due to exhaustion and impairment of the nutrition of the nerve-centers, while in a smaller contingent it takes the form of a true melancholia. After the conclusion of typhoid, as well as during its course, *neuralgia* affecting the occipital and other cranial nerves is not infrequent. Great hyperesthesia of the skin and muscles is common during convalescence, attacking the lower extremities by preference (Strümpell). The so-called "typhoid spine" (Gibney) has also been observed, and consists in an acute inflammation of one or more vertebræ following typhoid. The chief symptoms are pain in the back and hips of a lancinating character. The point of origin appears to be the small of the back; thence the pains extend paroxysmally up and along the spine and to the abdomen. They subside gradually, leaving the back weak and painful on attempts at turning in bed, etc. Plantar and other skin-reflexes are increased, and the knee-jerks are preserved. G. E. de Schweinitz has described at length the *ocular complications and sequelæ* of typhoid fever. Affections of the conjunctiva and cornea and retinal hemorrhage are perhaps the most frequent, although optic neuritis and affections of the uveal tract also occur.

(g) **The Urinary System.**—*Urine.*—The urine is lessened in quantity and high-colored, with an increased specific gravity up to the arrival of the stage of decline. About this time, and rarely earlier, it grows light in color, larger in quantity than the normal, and the specific gravity is relatively diminished. Both urea and uric acid are increased during the earlier stages, and sometimes throughout the attack, while during convalescence both are diminished. On the other hand, the chlorids are diminished during the active stages of the disease and increased during its decline. A *febrile albuminuria* is quite common, and the sediment may show an excess of renal epithelium, a few blood-cells, and occasionally renal casts.

Acute nephritis may develop as a complication in the earlier or later course of the disease, and can be recognized to a certainty only by a thorough appreciation of the urinary phenomena. The urine is diminished in quantity, being often scanty, and there may be retention. It contains characteristic morphologic elements (albumin, casts, blood, and epithelium). The development of the *typhoid state* in this affection is rendered much more probable in the presence of this complication, and, moreover, uremic symptoms often put in an appearance at this juncture, and then the situation is really serious. Acute nephritis may arise at one or other of three different periods, and its significance varies with the time of onset: (a) at the beginning of the fever, when it often obscures the true nature of the malady. This is the *nephro-typhoid* of the German authors, and will be referred to hereafter (*vide infra*, Varieties); (b) in the early part of the fastigium or the second week of the disease. Coming on at this time—an event which I have observed in two instances—it is probably to be ascribed to the local effect of the toxin upon the renal tissues. Both of my own instances proved fatal, and in both an autopsy was refused. Wagner¹ has had 5 cases of recovery in succession, but the high mortality mentioned by Amat—10 deaths in 12 cases—is the more common experience. (c) Acute nephritis may arise as a sequel of typhoid, when there is almost invariably associated a decided edema. In this category of cases recovery is to be expected.

The *diazo-reaction* of Ehrlich is a valuable aid in diagnosis, but may be present also in acute phthisis, meningitis, measles, pneumonia, yellow fever, and other fevers. To obtain it two other solutions (a and b) are needed: We mix 1 part of solution (a), which consists of a 0.5 per cent. solution of sodium nitrite, with 50 parts of solution (b), which consists of 2 grams of sulfanilic acid, 150 c.c. of hydrochloric acid, and 1000 c.c. of distilled water. To this an equal volume of urine is added, and the contents of the test-tube are then thoroughly shaken. A layer of ammonium hydrate is now superimposed, and at the line of contact a ruby or pink ring develops. A more reliable change, however, is a rose-red (pink) hue of the foam. Says Cummins, "Upon employing a dilution of 1:150 other conditions are eliminated (except a small percentage of tuberculous cases)." It is present in about 70 per cent. of the cases. The reaction begins about the beginning of the second week, sometimes later, and lasts usually until defervescence is well advanced. A brownish ring is given by normal urine.

Diabetes mellitus is, in extremely rare instances, developed after typhoid. Hematuria has also been observed as a symptom of the hemorrhagic diathesis.

There is a post-typhoid, diphtheritic *pyelitis* in which the pelves and calices of the kidneys are the seat of membranous exudation, and later of erosion and ulceration. The urine generally contains blood and pus.

Simple *vesical catarrh* may rarely result from catheterization for retention. Typhoid cystitis, in which the bacilli are found in pure culture in the urine, is not rare (*vide p. 53*). It occurs principally in patients who are predisposed by local conditions.

Orchitis, *epididymitis*, *spermatocystitis*, *prostatitis*, and *ovaritis* are

¹ *Deutsch. Archiv für klin. Med.*, Bd. xxv. and xxxvii.

occasional sequels. Blumenfeld collected 69 cases of orchitis; it generally develops suddenly during convalescence.

(h) **The Joints.**—Typhoid, septic and rheumatic arthritis may occasionally arise as a complication. The first is usually *mon-articular* (particularly in the hip); the last two commonly *polyarticular*. Keen has collected "in all 84 cases involving the joints."

(i) **The Bones.**—*Periostitis*, due to injury and muscular strain and often leading to *necrosis*, is a not rare sequel of typhoid. The favorite seats are the tibia and ribs, though in a case of my own at the Philadelphia Hospital it affected the os calcis. Ebermaier found the bacillus typhosus in the pus from 2 cases of suppurative post-typhoid periostitis, although other bacilli (streptococci, staphylococci, pneumococci) are at times associated. *Osteomyelitis* may also occur. Keen has collected 216 cases in which the bones were attacked.

(j) **The Muscles.**—As in the case of the heart, so the voluntary muscles exhibit hyaline degeneration; also abscesses, in consequence of secondary infection or of infection with the typhoid bacillus itself. Typhoid abscesses likewise result from perforations of the gut.

Associated Acute Infectious Diseases.—**Malarial fever** may be combined with typhoid, though the relationship is not a vital one. In an analysis of 2122 cases of malaria typhoid fever was associated in 8.¹ Many instances of so-called typhoid-malarial fever, however, would be shown to be pure typhoid by a careful blood-examination.

Pseudo-membranous inflammation, as above intimated, may occur in the naso-pharynx, larynx, gall-bladder, and genitals. *Measles*, *scarlatina*, and *chicken-pox* have also been known to arise in the course of, or during convalescence from, typhoid fever.

Erysipelas is a rare secondary affection coming on either during the height of the affection or (more frequently) after its close. Typhus fever may be associated with typhoid, but this is rare.

Clinical Varieties of Typhoid Fever.—These are numerous, and may grow out of peculiarities manifested during the course of the affection, as may be observed not only in different epidemics, but also in the same epidemic. The groups of cases described here have reference particularly to the degree of severity of the type, which varies between the wide limits of extreme mildness on the one hand and extreme severity on the other. The course of the disease may also be modified by the occurrence of one or more of its manifold complications.

(1) **The Mild or Rudimentary Form (Typhus Lævisissimus).**—Of this variety many cases occur, and especially among children. The spleen is almost always enlarged, the roseate spots are sometimes present, while the temperature is moderately elevated and often partakes of the same character as that of true typhoid. The fever, however, may pursue the remittent type. Complications presented by special organs are usually absent, but grave accidents (intestinal hemorrhage, perforation) are not impossible.

The *diagnosis* is always difficult, owing to the feeble development of the characteristic symptoms, and in the total absence of the latter is out of the question; but the recognition is assured if a casual connec-

¹ "The Complications of Malaria," *Journal of the American Medical Association*, vol. xxiv., p. 919, by the author.

tion between them and typical cases can be shown to exist, and if the Widal test gives a positive result.

(2) **The abortive form** has a sudden onset, and is often marked by fits of shivering. The characteristic features of the disease (enlargement of the spleen, abdominal symptoms, rose spots, etc.) appear earlier than in the usual type, and soon become quite well marked. The fastigium is short, and the temperature, from the seventh to the twelfth day of the illness, declines by a prompt lysis, with profuse sweating. With the rather rapid fall of temperature there is a no less rapid improvement in every other leading symptom. Convalescence is speedy.

(3) **The Ambulatory Form (Latent or Walking Typhoid).**—The patient continues to walk about, either experiencing but slight disturbance or being unwilling to take to his bed. Such cases do not come under the care of the physician in many instances. Others, on account of debility, anorexia, diarrhea, and other vague symptoms, finally consult their physician, who may discover the presence of all the characteristic features of the disease. A third contingent, belonging to this form, continue to move about, or even to follow their usual vocations, till seized suddenly with profuse intestinal hemorrhage or general diffuse peritonitis following perforation.

(4) **The afebrile** is an exceedingly rare form of the affection—in this country at least. Liebermeister, however, has met with a number of cases at Bâsle, the symptoms being lassitude, depression, headache, neuro-muscular pains, anorexia, slow pulse, furred tongue, constipation or diarrhea, with enlargement of the spleen and roseate spots. These cases are often confined to bed, and there are occasional attempts at evening exacerbations of temperature (100.5° F.—38° C.).

(5) **Severe or Grave Forms.**—These may be dependent either wholly or in great part upon the degree of virulence of the typhoid poison. A profound intoxication of the system, as shown by high temperature, violent nervous symptoms, and great prostration, is noted. The grave types may arise in the course of cases of average severity from the development of serious complications. Again, to serious forms belong those cases that begin with the characteristic symptoms of a localized inflammation—*e. g.* the *cerebro-spinal form*, in which the nervous symptoms greatly predominate at the onset; the *nephro-typhoid* (before alluded to), in which the preliminary symptoms are those of acute Bright's disease; the *pneumo-typhoid* (*vide supra*), which begins with the manifestations of a more or less frank pneumonia.

Pleuro-typhoid.—The cases begin as an acute pleurisy, and are followed, soon or late, by the diagnostic evidences of typhoid fever. Talamon¹ distinguishes these cases from simple pleurisy by the intensity and continuous course of the fever, by the general depression, headache, and vertigo, and by the sleeplessness. Eiselt² has described a special form under the name *spleno-typhoid*, in which the spleen is enormously enlarged without characteristic intestinal lesions. Perisplenitis with adhesions may be noted. The *sudoral form* and *tonsillo-typhoid* (before described) also belong to this category. The fever is often of remittent type.

¹ *La Médecine moderne*, Paris, 1891.

² *La Semaine médicale*, August 27, 1891.

Typhoid septicemia may present the grave symptoms of an extreme intoxication, often merging into the typhoid state. Visceral and cutaneous hemorrhages may be superadded. Cases of hemorrhagic typhoid fever have been reported by A. A. Eshner and T. H. Weisenberg¹ and others. They are probably due "to a condition of systemic intoxication and septicemia" (Nicholls and Learmouth). Many circumstances connected with the individual influence decidedly the general course of the affection, and these are based upon such factors as *age, habits, etc.*

(6) **Typhoid Fever in Children.**—The onset is rather more abrupt than in the adult, and certain prodromal symptoms are rarely present (epistaxis, chilliness). On the other hand, bronchial and nervous symptoms are often quite pronounced. Again, during the fastigium some of the usual typhoid features may be missing—*e. g.* diarrhea and tympanites—while the eruption may either be slight or absent. The disproportion between pulse-ratio and temperature is less marked than in adults (Butler). Intestinal hemorrhage is rare and perforation almost never occurs.

(7) **Typhoid Fever in the Aged.**—The course of the affection presents no regular type. The temperature is not as high as usual, but there is marked adynamia and serious danger from certain complications, such as pneumonia, nephritis, coma, and the like.

The diagnosis is difficult, owing to the prominence of the nervous and pulmonary symptoms on the one hand, and the frequent absence of the more characteristic symptoms of typhoid on the other.

Diagnosis.—Unless all the chief characteristic features be present with a clear history, it is a golden rule not to make a positive diagnosis. Obviously, then, the physician at the first visit, often about the close of the first week, cannot, in many cases, diagnosticate typhoid with absolute certainty. If the case have been a typical one, the history of the gradual development of the disease, marked by such symptoms as languor, anorexia, headache, dulness, slight chills, increasing fever, and sometimes nose-bleed, will be obtained, and justify a strong suspicion of typhoid. When, in addition, diarrhea and the objective symptoms, splenic enlargement, tympanites, gurgling, with tenderness in the ileo-cecal region, are present, the diagnosis of typhoid is made highly probable. After the lapse of a few days—the beginning of the second week—the roseate spots usually appear. The most certain method of making an early, positive diagnosis is by an examination of the blood for the bacillus typhosus. Mabee and Taft¹ have described the method of making blood-cultures from the ear, and found that in early cases of typhoid (*i. e.*, within the first week) an accurate diagnosis in from 90 to 100 per cent. is easily possible. Says Peabody,² while blood-culture in ox bile is the earliest indication, at a later stage, when the organism can no longer be isolated from the blood, the agglutination reaction (*vide infra*) is usually present. In obscure cases the occurrence of intestinal hemorrhage or a characteristic decline by lysis is helpful. To show a casual relation between an obscure case and one that is clearly typhoid leaves little to be desired. The diagnosis should include the particular stage of the disease. Briefly, the most trustworthy diagnostic features are the gradual onset, peculiar temperature-curve (made up of the "step-

¹ *Amer. Jour. Med. Sci.*, March, 1901.

² *Boston Med. and Surg. Jour.*, June 1, 1908.

ladder" stage of development, the continued type of the fastigium, and the decline by lysis), enlarged spleen, the rose-colored spots, cultural experiments, and the sero-reaction.

Serum-diagnosis.—Investigations by Pfeiffer upon the specific bactericidal substances developed in the blood of animals immunized by injection of typhoid bacilli have furnished a reliable means of diagnosis of this disease from blood-serum. It remained, however, for Widal and others to show that if to a drop of blood-serum, or to a drop of water containing a solution of dried blood from a typhoid patient, a moderate number of typhoid bacilli were added, a specific reaction occurred.

Johnston of Montreal has simplified the technic: The blood is obtained upon a clean glass slide from a needle-prick of the ear or finger of the suspected case. It is allowed to dry, and is then carried to the laboratory. A loop of bouillon-culture of genuine typhoid bacilli is placed upon a clean cover-glass, and to this is added a large loopful of a watery solution of the dried blood-specimen. The cover-glass is inverted over the concavity of a hollow slide and sealed at the edges with melted vaselin. Under the microscope, with a high-power dry lens or with a one-twelfth oil-immersion lens, a rapid clumping of the bacilli in the hanging drop can be observed,¹ and their motions cease almost instantly.

Diagnostic Value.—There is a general consensus of scientific opinion as to the great clinical value of the Widal reaction. The large statistics of Kneass and Stengel, based on 2283 cases, coupled with more recent available figures, show the presence of the reaction in 95.2 per cent., and no reaction in non-typhoid cases in 98 per cent.

Of 230 cases examined, 219 gave a positive result (Anders and McFarland²). In 128 of these cases this result was obtained prior to the appearance of the rose spots, or before the eighth day; in 36 cases the first reaction occurred during the second week; in 45, between the seventeenth and twenty-first days of the disease; in 8, not until the twenty-fifth day, and in 2 cases as late as the twenty-eighth day.

Interfering Conditions.—In the first place, a previous attack of typhoid fever may produce a reaction. In 39 cases of pure typhoid tested at periods of from one to eighteen months after defervescence, 13 reacted positively (Cabot and Lowell). It may be possible for the scene to be dominated by some other morbid process (tuberculosis, etc.). Kraus³ found that a complicating pneumonia caused the Widal reaction to disappear. Again, exceptional cases occur with no reaction throughout. Brill has reported 17 cases of this sort; in such cases, however, the examination must be repeated until after convalescence is completed. A. C. Abbott⁴ reports that, according to the records of Widal reactions carried out in 4154 cases in the city laboratories of Philadelphia, the error does not exceed 2.8 per cent.

Conradi⁵ has discovered a new method of cultivating typhoid bacilli. A small amount of blood is obtained by lancing the ear; this is inoculated into a small sterile bottle of bile, to which a little peptone and glycerin has been added. After sixteen hours the bile is reinoculated onto lactose-litmus agar. A positive diagnosis can be made in thirty hours.

⁵ *Münch. med. Wochenschr.*, 1906, vol. liii., p. 1654.

Chantemesse¹ suggests an ophthalmic test, but the cutaneous reaction is a more simple test and "gave positive results in every case in which it was employed" (Deehan).

The cases that begin with the well-defined local inflammatory lesions previously referred to (tonsillo-typhoid, pneumo-typhoid, pleuro-typhoid, nephro-typhoid) cannot be recognized at the outset. The same local inflammatory conditions may, independently of typhoid fever, be combined with a genuine typhoid state. In all instances of typhoid fever in which, at the time of onset, localization occurs, the degree of fever and prostration are apt to be out of proportion to the local symptoms, and the former are apt to continue after the subsidence of the latter. A careful observation of the symptoms after the first week will usually detect undoubted symptoms of typhoid. I have found that the Widal test decides many of these cases. Blood-cultures if made early will also set the diagnosis at rest. The bacilli may be obtained from the stools.

Differential Diagnosis.—(1) **Typhus fever** (rarely met with) is to be differentiated by its appearance as an epidemic, by its sudden onset, by the deeper stupor, the besotted expression of the features, the injected conjunctivæ, the contracted pupils, the appearance on the fourth day of maculæ which are transformed into petechiæ; by the shorter course, the termination by crisis, and the absence of the Widal reaction.

(2) **Acute military tuberculosis** has been, and still is, frequently mistaken for typhoid fever. The former is to be differentiated from the latter by the greater frequency of the pulse and respirations, the prominence of the cough, and in some instances by the bloody expectoration; by the diffuse cyanosis, and the presence (sometimes) of choroidal tubercles. *Blood-examinations* may show leukocytosis, but the large mononuclears are not increased as in typhoid fever. There is an absence of the peculiar temperature-curve, the pulse, the characteristic lenticular spots, and the Widal reaction and abdominal symptoms of typhoid. In doubtful cases lumbar puncture and blood-cultures should be undertaken, as tubercle or typhoid bacilli may be found.

(3) **Malarial fever** may assume the continued form of fever—*e. g.*, the æstivo-autumnal type, in which chills may be absent—and there are typhoids that affect both remittent and intermittent malarial fevers. Malaria can be differentiated from typhoid fever only by the detection of Laveran's hematozoa in the blood.

Should *typho-malarial fever* be suspected and the typhoid symptoms be unequivocal, the finding of the malarial organism would establish the diagnosis and differentiate the hybrid from pure typhoid.

(4) **Relapsing fever** is distinguished by its abrupt onset, with rigor, high fever, pain in the epigastrium; by its brief duration, termination by crisis, and the occurrence of a relapse at the end of a week; by the absence of the characteristic eruption and the sero-reaction of typhoid. The finding of the spirilla reliably discriminates relapsing fever.

(5) **Meningitis.**—In striking contrast with the specific typhoid symptoms, meningitis exhibits marked hyperæsthesia, intolerance of light and sound, exaggerated reflexes, and often muscular rigidity before the

¹ *Progressive Medicine*, March, 1910, p. 186.

stage of effusion; also restlessness, peevishness (unlike the dulness observed in typhoid patients), vomiting, and constipation (*vide* Acute Miliary Tuberculosis). The temperature maintains a lower level on the average, and is more irregular in type than in typhoid; the pulse is more irregular, and the nervous symptoms assume greater prominence in the earlier stages, particularly headache and delirium. On the other hand, true typhoid symptoms are wanting in meningitis.

(6) **Tuberculous meningitis** gives a characteristic previous or family history, occurs in young subjects, and the tendon and cutaneous reflexes exhibit wide variations as to intensity, within brief periods and throughout the whole attack. An examination with the ophthalmoscope may reveal choroidal tubercles. The Widal reaction is missing.

(7) **Catarrhal enteritis** in children, with prominent abdominal symptoms, may simulate typhoid fever very closely. In the former the symptoms are all gastro-intestinal, save perhaps the occurrence of slight febrile disturbance and certain nervous phenomena, while typhoid fever manifests a wider range of symptoms (some of which are peculiarly its own—notably the greater prostration, more marked fever, enlargement of the spleen, the sero-reaction, and the characteristic eruption). In young children the last-named symptom may be either wanting or atypical, in which case the existence of enlargement of the spleen coupled with other phenomena, particularly the Widal reaction, will suffice.

(8) **Salpingitis** on the right side may resemble typhoid. In the former there is usually a clear history either of antecedent vaginitis or of an abortion, and there exist special evidences of local peritonitis, with which may be associated the typhoid state, but not the classic features of typhoid fever. A digital examination *per vaginam*, however, is necessary to the certitude of diagnosis in salpingitis.

The diagnosis between typhoid fever and *typhoid pneumonia*, *influenza*, *ulcerative endocarditis*, and *appendicitis* will be considered hereafter.

Prognosis.—As in all other acute infectious diseases, so in typhoid, the prognosis depends upon three main considerations:

(1) The severity of the type of the infection, which is indicated in great measure by the degree of fever. A temperature of 106° F. (41.1° C.) is a serious symptom, and, if maintained at this point for a few days, an almost certainly mortal one. I have not seen a single instance in which the temperature has touched 106° F. (41.1° C.) for two or three successive days that has recovered. If the temperature mounts to and keeps at 105° F. (40.5° C.) for more than three or four days, the prognosis should be made with due reserve. Temperatures above 106° F. (41.1° C.) I would regard as offering no hope of recovery. When the fastigium is much prolonged, even though the fever be not exceptional, the prognosis is usually grave; while, on the other hand, marked nocturnal remissions are of favorable omen. A sudden, deep fall, however, may imply danger (intestinal hemorrhage, collapse).

The researches of Isaac Ott have taught us not only that fever is due to an agent from within or without, which deranges the harmony of the thermotaxic, thermogenetic, and thermolytic apparatuses, increasing primarily tissue-metabolism, but also, that while high temperature is an

indication of danger in specific fevers, it is not always the cause of it. He regards high temperature as being only a part of an infectious process, and points out that the thermotaxic centers of the cortex may be so disordered as to alter the harmony between the heat-production and heat-dissipation. Under these circumstances a specific fever of severe form may be associated with a slight elevation of temperature.

The power of resistance to the influence of high temperature is quite reliably indicated by the condition of the heart. So long as the pulse is regular and its rate does not exceed 110 or 120 beats per minute, the outlook is favorable. When, however, the pulse maintains an average rate of 130 or more—a condition with which there is usually associated some degree of cyanosis, pulmonary congestion, and edema—the outcome is to be regarded as doubtful. Collapse is apt to follow the occurrence of sudden complications (perforation, hemorrhage), but it may also arise causelessly. The absence of eosinophiles from the blood-picture is an unfavorable prognostic sign.

Serious types are also shown by certain nervous symptoms, such as wild delirium, stupor, and well-marked symptoms of motor irritation.

(2) **Circumstances of the Patient.**—Certain individual peculiarities render the prognosis highly unfavorable. It is *bad* in very *fat* persons. In such cases there is a great and constant danger of sudden collapse, and this fact also holds to a less degree with reference to those persons who are subjects of certain chronic diseases (Bright's disease, heart-disease, gout, emphysema).

Age is an influential modifying factor. After puberty the gravity of the disease increases with increasing years. Indeed, it may be said that, as a rule, typhoid has an unfavorable prognosis in persons past forty years, and chiefly for the reason that at this time of life there is an added liability to pulmonary complications and failure of cardiac reserve. In children (*vide* Clinical Varieties) the tendency to hemorrhage and peritonitis is reduced to a minimum, and the mortality is not over 1 per cent.

The **puerperal state** renders a typhoid patient liable to many accidents and peculiar complications, and it seems that independently of pregnancy the disease is more fatal among females than males. *Chronic alcoholism* is apt to be complicated with *delirium tremens*, often preceded by *pneumonia*. Such patients are also prone to heart-degeneration and exhaustion.

Environment affects the prognosis, poor sanitary arrangements and poor attention greatly diminishing, and the opposite conditions greatly augmenting, the chances for recovery. Improved methods of treatment in recent years have effected a decided lowering of the death-rate. Here it may be said that the average mortality rate of typhoid is from 8 to 10 per cent., as against 15 to 20 per cent. formerly. The death-rate was 2.3 per cent. lower among the inoculated South African soldiers than in the uninoculated. It must ever be remembered, however, that epidemics differ widely as to their mortality list—a fact which makes a precise statement regarding the question an impossibility.

(3) The third and last consideration is the **presence or absence of dangerous complications and accidents**. These have all been enumerated and their prognostic significance stated (*supra*). Merely to reiterate

some of those that lend fresh peril to the typhoid patient, arranging them with some regard for the order of their relative gravity, may prove helpful to the student. They are—perforation with diffuse peritonitis, intestinal hemorrhage, lobar pneumonia, lobular pneumonia, sudden collapse (due to cardiac weakness), excessive tympanites (often with marked diarrhea), and hypostatic congestion of the lungs.

RELAPSES OF TYPHOID FEVER.

A relapse is a repetition of all the characteristics of typhoid after the latter has run its course. As a rule, the return occurs from one week to ten days after the beginning of convalescence, though it may be either earlier or later; and occasionally a relapse develops before the temperature has become normal (*intercurrent relapse*). The cause of relapses is a reinvasion of the blood by the typhoid bacilli or their secretions from within the body, and the source of the bacilli is most probably the gall-bladder. The *pathologic lesions* differ in no essential way from those described as belonging to the primary attack, but the stages through which they pass are not quite so long.

In the *interval* between the primary attack and the relapse there may be present suspicious features, such as a slight enlargement of the spleen, a trivial evening rise of temperature, an unnatural apathy or dulness, and a more profound prostration than is usual. In the majority of instances, however, there are no premonitory symptoms. The *onset* is rather more sudden, and rigors are more common, than in primary typhoid. The temperature, however, rises in the characteristic “step-ladder” fashion, reaching the fastigium in two or three days, and the same relative abridgment of the fastigium and defervescence is observed. It follows that a relapse has a shorter duration than a primary attack, and, indeed, it rarely exceeds two or three weeks. The temperature may, however, touch a higher limit in the relapse than in the primary attack; but, with rare exceptions, when the primary typhoid is of average or even greater than average severity, the temperature in the relapse does not reach an equal height. The characteristic rash appears earlier—from the second to the fourth day—and is somewhat darker and coarser than that of the first attack. The spleen swells rapidly. The *intercurrent relapse* sets in while the temperature is declining; the fever again rises, and often ranges higher than in the primary attack.

Diagnosis.—Upon the points that are distinctive of a primary attack of typhoid fever rests the important diagnosis between a relapse and a recrudescence (*spurious relapse*). The latter is usually attributable either to errors in diet, to undue muscular exertion, or to great mental excitement; and, whilst it occurs during convalescence, it seldom lasts longer than one, two, or three days, and is not characterized by the diagnostic symptom-group of a relapse (peculiar temperature-curve, enlarged spleen, and specific eruption).

The **prognosis** of relapses depends very much upon the severity of the primary attack, those following severe attacks being relatively milder than those that follow the rudimentary, primary attacks.

The frequency of relapses differs widely in different epidemics.

Hence the fact that the percentage of relapses as estimated by different authors ranges from 3 to 15 per cent. need excite no surprise. The relapse may repeat itself once, twice, or even thrice, and two relapses occur in about 1 per cent. of the cases. In a case which I¹ reported three successive and typical relapses occurred. The pale line or ridge which was mentioned (*vide* Clinical History) as noticeable in the nails after typhoid occurs similarly after each relapse, and in the aforementioned case of my own four distinct whitish, transverse ridges were noted. Da Costa has recorded five relapses in each of two cases.

Recurrences.—By this term is meant successive attacks separated by longer or shorter intervals after complete recovery from the primary attack. Typhoid fever usually bestows lasting immunity, but this is not an invariable rule. Eichhorst has studied 600 cases, and found that in 28 of the number (4.7 per cent.) a second attack occurred. Soldiers who are subjected to typhoid fever, commonly give a history of previous attacks (D. Parker). I have seen a number of typical recurrences of typhoid fever, in two persons, the intervals having been five and eight years respectively. Very rarely three separate attacks have occurred in the same individual, and a second is usually milder than the first attack.

Treatment.—(a) **Prophylaxis.**—The municipal authorities possess in thorough filtration a power that might and should be used to advantage, as has been well shown by the improvement effected in certain water-supply and sewer systems—*e. g.*, in Vienna—where by purification of the water-supply the death-rate in typhoid fever was reduced from 12.5 per 10,000 to 1.1 per 10,000.

It has been well said that typhoid bacilli do not naturally inhabit water and milk, although, as stated above, they may exist and even multiply in these media, but man is their natural host, hence the primary source of the bacilli. Let us make sure that every typhoid bacillus is killed immediately on leaving every host and the disease is at an end. (McCrae).

The best means that can be employed during the attack, with a view to limiting the spread of typhoid, is *disinfection*, and the following brief description comprises its essential points as applied to this disease:

Disinfection in typhoid may conveniently be divided into (a) that of the excreta (stools, urine, vomitus, and sputum); (b) of the bed and its coverings; (c) of the patient and the sick-room. While all of these subdivisions are of the greatest importance in the treatment of a case, *the disinfection of the excreta* (a) is perhaps most carelessly performed, and hence the importance of the statement that all stools and urine voided by the patient, as well as the vomitus and sputa, should be promptly treated as follows: The excreta should be received in a vessel that can be thoroughly disinfected inside and out with any of the several standard solutions, of which that of chlorinated lime (strength, 6 ounces per gallon) is the most effective and satisfactory. Bichlorid of mercury (1:500) may be used, but, as it requires a much longer time and forms an insoluble compound with the albumins in the feces and sputa, it is inferior to the solution of chlorid of lime. A 5 per cent. solution of carbolic acid is also employed.

¹ *Med. and Surg. Reporter*, vol. xlvii., p. 66.

It is my custom to order that one pint of the chlorinated lime solution be placed in the bed-pan (or other appropriate receptacle) *before* the discharges are received therein, and from one to two pints *after*. The whole is thoroughly mixed by stirring and shaking, care being taken that all solid masses are broken up. The vessel is then allowed to stand for three hours before it is emptied into the water-closet. Klemperer recommends a 1 per cent. solution of chlorid of lime. If the mercuric-chlorid solution be employed, at least six hours must be allowed for thorough action upon the excreta. The urine must be treated in the same conscientious manner as the feces.

Gwyn¹ has given the results of most recent investigations into the question of typhoid bacilli in the urines of typhoid-fever patients: They are present in from 20 per cent. to 30 per cent. of the cases, and may be exceedingly numerous. The organisms may persist for months or years. For the disinfection of the urine in the bladder, urotropin is serviceable when administered by the mouth. As an irrigation, Gwyn recommends mercuric-chlorid solutions (1 : 100,000 to 1 : 50,000).

(b) It should be an invariable rule to change the bed- and body-linen daily, and as often as soiled. The mattress should be protected by a rubber cover, and this, together with the soiled linen and blankets, should be received in a sheet that has previously been dipped in a 5 per cent. solution of carbolic acid. The rubber sheets are to be washed with the carbolic-acid solution, but all other bed-clothes must be boiled for half an hour. When the patient leaves the sick-room the mattresses are to be fumigated and aired daily for a week, and the rubber covers and bedsteads washed with a solution of mercuric chlorid (1 : 1000).

(c) After every stool the patient should be cleansed with a compress of cloth or cotton wet with a solution of mercuric chlorid (1 : 2000) or of carbolic acid (1 : 40). The bed-pan and hopper are to be similarly treated, and the cloths used immediately burned. Fitz recommends that the feeding utensils be cleansed in boiling water after using.

Since it is well known that many epidemics are directly traceable to the drinking-supply of water and milk, it is necessary that all water and milk used by the patient and other members of the household be boiled for half an hour before being ingested; and if an epidemic be prevailing, the community at large should join in this precaution.

Isolation of Patients.—It is advisable to isolate typhoid cases as far as possible—*e. g.* in hospitals, to keep them in special wards; in private families, in special apartments. There is incontestable proof that typhoid fever is feebly contagious.² At the Johns Hopkins Hospital 1.81 per cent. of all cases are of hospital origin (Cole).

Prophylactic Inoculations.—Encouraging results have also followed the *preventive inoculation* of healthy persons with typhoid virus, and Pfeiffer believes that this mode of prophylactic treatment promises to render great service in future epidemics. A. E. Wright, during the siege of Ladysmith, reports 10,529 men not inoculated. Of these, 1489 developed typhoid fever, with 329 deaths. Of 1705 inoculated men, 35 developed typhoid, with 8 deaths.³ Major Russell inoculated 10,000

¹ *Philada. Med. Journ.*, January 12, 1901.

² *Philada. Hosp. Report*, 1891, vol. i., p. 149, by the writer.

³ "History of Typhoid Fever, with Statistics," *Pennsylvania Med. Journ.*, Nov., 1900, by the writer.

men, of whom only 56 developed typhoid, with 5 deaths, and nearly all the cases in the inoculated men occurred in those who had had but one injection, while all 5 deaths were among them. Irwin and Houston successfully treated a case of persistent typhoid bacilluria by means of a vaccine prepared from typhoid bacilli.

(b) **Treatment of the Attack.**—(1) The **general conduct** of the case, including skilful nursing, is of paramount importance to the typhoid patient. He should be put to bed as soon as the indications point to this disease, and kept there continuously in the recumbent posture till the end of the attack. The sick-room should have a sunny exposure if possible; should be cool and well ventilated, though free from strong currents; and perfect cleanliness both of the room and of the utensils employed in the management of the case should be attempted. The bed should be provided with a woven-wire mattress, upon which should be placed one of hair. A rubber cloth is spread beneath the sheet, and the latter kept smooth in order to lessen the danger from bed-sores. A seriously ill patient should lie on an air-cushion or, better still, a water-bed, and to avoid bed-sores he should be instructed to turn gently to either side from time to time. His back, hips, and heels should be bathed frequently with a mixture of alum and salt in dilute alcohol. The use of the bed-pan and urinal is an absolute necessity. When a good nurse cannot be had, the attending physician must note *in writing* the directions regarding the disinfection of the excreta, bed-linen, and utensils, as well as regarding the exhibition of the food, medicine, etc. The mouth and throat should be kept clean, since by so doing we obviate unpleasant and even dangerous complications (aphthous ulcer, thrush, parotitis, lobular pneumonia, etc.). In the latter the nurse or attendant should wash the mouth and tongue several times daily with a solution of boric acid (3 per cent.), and the throat may be sprayed at equal intervals with a similar solution. A frequent moistening of the tongue and mouth, and particularly the lips, with glycerin and water (equal parts) gives great comfort when they are dry and parched.

(2) An **appropriate liquid diet** should be employed, and the best article of food is milk, which it is well to dilute with plain water (or lime-water), since aerated waters are objectionable in that they sometimes increase the meteorism. The daily quantity should not be less than three pints, and it is important that the stools be examined, since, if the milk be not thoroughly transformed, curds or (on microscopic examination) numerous fat-globules will be seen, in which case a smaller amount should be given. If curds or fat are still seen, the milk should be peptonized. Experience teaches that milk is often better taken and better borne when a little brandy, coffee, or tea is added to it. When milk cannot be taken or digested in sufficient amount, either whey, sour milk, or buttermilk may be tried; and if these be distasteful, we may replace them (wholly or in part) by meat-juices or broths of various sorts, together with one of the standard infant's foods made with milk or water. Albumin-water, prepared by straining egg-white through a cloth and adding an equal part of water, has given much satisfaction in my hands. It may be made pleasant to the taste by flavoring with vanilla or lemon, and with meat-juice and broths will often support a patient during the most trying period of the attack.

William Coleman recommends carbohydrates, which protect body protein better than any other foodstuff, in the form of milk-sugar, the latter being smaller in bulk and less likely to disturb the digestion than starches. There are typhoid subjects who cannot (on account of vomiting, etc.) take *per oram* sufficient nourishment to support life. In such cases we may supplement the usual method of feeding by rectal alimentation, when from 3 to 4 ounces (96.0–128.0) of peptonized milk, $\frac{1}{2}$ ounce (16.0) of meat-juice, and a little egg-white may be combined, and employed at intervals of four hours. In early convalescence the patient may take milk toast, well-cooked plain rice, entire eggs (diluted), or thin custards. Solid food should not be allowed till the temperature has been at the normal grade for one week at least. In cases in which the fastigium tends to become prolonged with increasing prostration, and those presenting the fever of exhaustion, the administration of soft food (eggs, finely scraped meat, well-cooked rice, plain) is often followed by improvement.

Pure cold water has a positive value as a diuretic in this disease. Cushing and Clarke¹ used large quantities of water internally (a gallon or more in twenty-four hours), administering it in small quantities at frequent, definite intervals. The toxic symptoms and mortality were lessened. The internal use of water stimulates renal activity by raising the blood pressure. Coffee, tea, and lemonade, sweetened with glycerin or saccharin, are admissible.

(3) **Stimulants** are useful in about 50 per cent. of the cases. When the first heart-sound becomes weak or the vascular tone diminished, alcohol should be used regardless of the temperature. In severe types whisky is the best form; in milder ones some good wine, such as port, sherry, or madeira. It is well to begin with a moderate daily quantity, and then increase, if necessary, until the indication is fulfilled. If the patient so desires, we may use brandy instead of whisky, and it is usually toward the close of the second or during the third week of the disease that the indications for the use of alcohol arise. It is not only the best spur for a flagging heart, but is of equal value in combating unfavorable nervous symptoms due to the typhoid septicemia; and the time for commencing its use may be indicated first by the latter symptoms (*e. g.* delirium, coma, tremor). The quantity to be administered must be regulated by its effects, since it may act injuriously, and even aggravate the symptoms, though this is seldom the case. Threatened collapse may be met by full doses of alcohol ($\frac{1}{2}$ ounce—16.0—every hour), combined with strychnin (gr. $\frac{1}{15}$ —0.004—every three hours), exhibited subcutaneously till the depression has been counteracted. Effective doses of diffusible stimulants, as champagne, are useful during periods of sudden circulatory depression. The cardiac stimulants mentioned above may be further supported by the use of digitalis and sulphuric ether. Stengel has recommended hypodermic injections of 1 to 2 grains (0.0648–0.1296) of camphor dissolved in 15 minims (1.0) of sterilized olive oil as a cardiac stimulant in typhoid fever.

(4) **Hydrotherapy.**—There is at the present day general agreement among medical authors that the best mode of treating typhoid fever is by means of the *cold bath*, which was originally introduced by Currie, of London (more than a century ago), and reintroduced and successfully

¹ *Amer. Jour. Med. Sci.*, February, 1905.

practised by Brand of Stettin. There are obstacles in the way of carrying out hydrotherapy in private families, but since convenient and inexpensive portable tubs have been devised most of the valid objections to the method have been removed. At all events, the benefits offered to the patient by this method are so great and varied that it becomes the duty of every physician who treats typhoid fever to be prepared to employ it. The beneficial influences of the baths are as follows: (1) They absorb the body-heat directly, thus reducing the temperature and overcoming the ill effects of high fever, this action becoming more marked after a day or two of the treatment; (2) They improve the nervous symptoms, diminishing mental dulness, delirium, stupor, muscular tremors and twitchings, and inducing sleep; (3) They strengthen the heart, thus obviating the danger of sudden circulatory collapse and the consequences of increasing cardiac weakness (hypostatic congestion of the lungs, venous thrombosis, etc.); (4) They stimulate the respirations, whereby the inspirations are deepened and the tendency to pulmonary complications greatly lessened, especially severe bronchitis, lobular pneumonia, etc.; (5) The renal function is invigorated, and as a result the elimination of typhotoxins by the kidneys is increased (Roque and Weil); (6) On account of the cleanliness of the skin which they ensure, bed-sores rarely occur; (7) They may shorten the stay in the hospital or sick-room, but not the stay in bed, except, perhaps, in the lighter types.

Unquestionably, the good effects of the Brand method receive striking confirmation from statistical reports which have been prepared by Brand himself, Jürgensen, and others abroad, and by Baruch, Osler, Wilson, and others at home. According to the warmest European advocates of the method, the mortality is less than 0.5 per cent., and no deaths occur in cases that come under treatment before the fifth day. The results among American clinicians give an average mortality of 7.3 per cent. Of 102 cases of my own treated by cold and by graduated cold baths, 8 died—giving a death-rate of 7.8 per cent. During five years 408 cases have been treated by the bath-method in the Royal Victoria Hospital, Montreal, with a mortality of 4.4 per cent.

The tub is to be brought to the bedside of the patient, and in hospital practice both bed and tub should be screened while the bath is in progress. After removing the night-dress and placing a large napkin around the loins, the patient should be lowered into the bath by a sheet held at each corner by an attendant (and, if seriously ill, with the least possible disturbance), and there carefully supported and held while in the bath. If sleeping, the patient must be awakened and the bath delayed for ten or fifteen minutes. Young subjects and adults in light cases of the disease may be handled properly by two persons, but I do not approve of allowing the patient to step from the bed into the bath, however light the case. While in the bath the skin-surface, particularly that of the back and limbs, is constantly rubbed by the attendants, in order to stimulate the peripheral circulation and as far as possible to avert chilliness and discomfort. The head of the patient rests upon a rubber air-cushion. At first he should be kept in the bath five to eight minutes; later, ten or fifteen minutes, according to the severity of the case. The head and face are bathed at once from a basin, and a

FIG. 5.—Chart illustrating the influence of cold baths in the treatment of typhoid fever.

cold compress is applied to the forehead, and, if prominent nervous symptoms be present, often associated with high temperature, water at 70° F. (21.1° C.) or lower should be poured from an elevation of about six inches upon the head and nape of the neck several times during the bath. The ears must be stopped with cotton when douching is practiced. If while in the water the patient complains bitterly of the cold or is very restless, a stimulant may be administered—f3j (32.0) of whiskey, diluted—and if this fails he must be lifted into bed and further stimulated. If he be very young, highly sensitive, or elderly, it is best to place him at the commencement in water of a temperature of 85° or 90° F. (29.4°–32.2° C.), and then gradually cool it down to 80° F. (26.6° C.). After he has become accustomed to the bath he may be immersed in water at the temperature of 80° F. (26.6° C.), to be reduced to 75° F. (23.8° C.) or even 70° F. (21.1° C.), below which it is unnecessary to go save in the rarest instances. This is the *gradually cooled bath* of Ziemssen. In the rigid Brand method, which is, perhaps, less generally adopted at present than several years ago, the patient is lifted at once into a bath at 70° F. (21.1° C.) and kept there for fifteen minutes. He is to be removed from the bath to the bed (previously protected by a blanket and mackintosh), wiped off gently; after which the sheet, blanket, etc., are withdrawn and he is covered with a fresh blanket. If now reaction be retarded, some hot broth or about an ounce of whisky should be administered and active friction applied to the back and extremities.

The effect of the bath is best shown by the rectal temperature, which is taken half an hour after the conclusion of the bath, and again a half hour later if the patient be not asleep. Usually the temperature will be found to be two or three degrees lower than before the plunge

FIG. 6.—Portable bath-tub in use.

(see Fig. 5). In obstinate and severe cases the fall may be less than one degree, in which case it is advisable either to prolong the bath to twenty minutes or to reduce still further the temperature of the water. Protracted warm baths are highly recommended by Reisse and others when cold baths are badly borne or are unproductive of good results.

In light cases the cold bath should be repeated every six or eight hours; in severe ones, every three or four hours, but more frequently than once in three hours is not advisable, even in the worst cases.

Sufficient water to immerse the patient to the neck (about 30 gallons—114 liters) should be used. During the night the patient should be allowed to sleep for six or eight hours if he can do so.

There are a number of convenient and satisfactory portable tubs in the market, but that devised by Dr. C. L. Furbush of Philadelphia possesses certain leading advantages (Figs. 6, 7). The frame is made of light wood, and when folded is 4 inches (10.156 cm.) in

FIG. 7.—Portable bath-tub, folded.

depth, 14 inches (35.546 cm.) in width, and 5 feet 10 inches (1.778 m.) in length, so that it can be placed in a closet or beneath a bed. Less than two minutes are required to prepare the bath, which the patient receives while lying in bed. When in use the ends are fastened by brass pins hung on small chains, and these hold the frame in a fixed position. The tub proper is made of double-faced sheeting, reinforced in the middle, so as to resist the greatest amount of pressure. The sides of the sheet have a casing through which is passed a wooden rod 4 feet 4 inches long (1.320 meters), and outside of this a margin of $1\frac{1}{2}$ inches (3.808 cm.) is left for the brass eyelets, through which passes a rubber cord which is covered with woven cotton. This cord, which is attached to the sheet, is held to the frame by special brass fittings along the lower sides of the latter. By the use of the cord and wooden rods we have an even tension on both sides, combined with ample resistance to withstand the pressure of the water. An adjustable head-rest fits into the end of the frame. The wooden rod also enables the attendant to roll up the sheet quickly after the bath. Through the bottom of the sheet a 1-inch rubber tube is fitted with a stopper, and by means of this the tub can be emptied sooner than by a siphon. The frame is covered with ivory-enamel paint, and can be cleansed easily. The entire weight of the outfit is 25 pounds (11.33 kgms.).

Brand recommends that the baths be commenced when the temperature in the rectum reaches 102.2° F. (39° C.). The height of the temperature, *per se*, is not to be invariably regarded as an absolute indication for the employment of the cold bath, since the facts must be recollected that the essential effect is a stimulation of the nerve-centers which preside over the organic functions (respiration, circulation). Moreover, cold baths exert a marked preventive effect in obviating

serious symptoms and complications. I continue the baths until the evening temperature remains below 101° F. (38.3° C.).

The *contraindications* to the use of baths are—(1) *Intestinal hemorrhage*, which is in itself attended with danger and requires absolute quiet for a time (four days), when the baths may be resumed if there is no recurrence. (2) *Peritonitis*, the occurrence of which always excites suspicion of perforation. Here, again, rest and all that the term implies must be procured. (3) *Extreme Cardiac Weakness*.—The excitement in the necessary handling of the patient connected with the bath might prove fatal, as I have witnessed in one instance. This condition is sometimes met with in cases that come under observation at a late period, and in cases arising in aged and enfeebled subjects. (4) Cases that have progressed to an advanced stage (the third week of the disease) should not be immersed. Dangerous and even fatal collapse has been observed to follow cold baths under these circumstances.

Substitutes for the Cold Bath.—The prejudice which exists against the cold-bath treatment—at least in America—sometimes proves insurmountable. Again, there are many physicians who do not avail themselves of the means at command for carrying out hydrotherapy. In consequence of these facts substitutes for the tub baths are quite commonly in vogue. Among them, cold sponging of the body of the patient is often resorted to, though it secures for him trivial advantages as compared with those of the baths. If this method be employed, the water should be of the temperature of the air of the room or ward. The limbs should be sponged and dried in succession, and then the trunk. Whenever the temperature reaches 102.5° F. (39.1° C.) this measure is to be instituted, each sponging being continued until the desired effect has been produced (a reduction of the temperature of $1\frac{1}{2}^{\circ}$ to 2° F.— 1° C.), unless the patient gives signs of uneasiness, when it must be cut short. It may be repeated as often as required. To the water used equal parts of vinegar or spirits should be added. The efficacy of the cool sponging is enhanced by the simultaneous application of the ice-cap, either constantly or intermittently.

If this method fails, as it often does in severe types, the cold pack may form a satisfactory substitute; and I have found it of great use with children, in whom the reaction after a cold bath is often delayed or imperfect. The patient is placed upon a cot previously prepared by spreading over it a blanket, which is in turn covered with a sheet doubled and wrung out of water of the required temperature— 70° to 80° F. (21.1° – 26.6° C.). The sheet and blanket are now wrapped about the patient evenly, and he is left in the pack for a period varying from a half to one hour. Free diaphoresis generally ensues, and this aids in maintaining the fall of temperature. The effect, in most instances, is to reduce the body-heat two degrees or more, and the treatment may be repeated at intervals of three or four hours if needful. The wet sheet alone may surround the patient, and be sprinkled at short intervals with a watering-pot containing water at a temperature of 70° F. (21.1° C.). In desperate cases ice-water enemata may be tried. If carefully administered they accomplish a reduction of the temperature by two or more degrees. Leiter's coils may be applied to the head, chest, or abdomen.

Guaiacol has been used for its antipyretic effect by H. G. McCormick and others, from 10 to 30 minims (0.666–2.0) being applied to the skin surface. I have seen its use followed by rigors, hyperpyrexia, etc., but McCormick uses sufficient only to lower the temperature to 100° F. (37.7° C.), and has thus avoided all ill effects.

(5) **Internal Antipyretics.**—The most reliable of this group of medicaments (phenacetin, acetanilid, and antipyrin) are open to the serious objection that they depress cardiac power. Since heart-enfeeblement, which may develop either gradually or suddenly, is recognized by present-day clinicians as a common danger-signal of the disease, the time has come when the employment of coal-tar products should be discontinued.

(6) **Intestinal Antiseptics.**—Unquestionably these neither destroy the bacilli nor counteract the ill effects of their toxins, since both become active after they pass beyond the intestinal mucosa; but they are indicated in cases in which tympanites is a prominent manifestation. Some of the toxic substances occupying the intestines in this disease result from the acquired virulence of usually harmless organisms, and the amount of decomposable material is increased owing to defective hepatic and gastric secretions. Salol is broken in the intestinal canal into carbolic and salicylic acids, and has proved capable of controlling meteorism as nothing else has done in my hands. The dose is 2 to 3 grains (0.1296–0.1944) every three hours, preferably administered in capsule. With it I usually combine quinin in doses of 1 to 2 grains (0.0648–0.1296) each. Henry speaks in favor of thymol, and guaiacol carbonate has many advocates. Wilcox¹ urges that chlorin is capable of disinfecting the intestinal tract. Acetozone in daily doses of 15 to 20 grains is both an efficient and harmless intestinal antiseptic; it should be dissolved in a liter of water, flavored with some one of the volatile oils, and taken in divided portions. Systematic lavage of the intestinal tract is advisable in excessive tympanites. In cases in which pronounced meteorism occurs the use of hydrochloric acid in small doses after each feeding is serviceable, since the secretion of this agent, which normally inhibits putrefactive changes, is lessened.² Mild purgation with calomel, especially in the earlier stages, is useful. Carbolic acid, iodin, sulphocarbonate of zinc, and other antiseptic agents have their advocates.

Turpentine fulfils in some cases a leading indication. When the tongue is dry and brown, the abdomen distended, the general prostration marked, and often muttering delirium present—symptoms of the typhoid state—the use of this agent, together with alcoholics, constitutes the best mode of treatment. Of the rectified oil of turpentine \mathfrak{M}_{v-x} (0.333–0.666) may be administered every third hour until relief is afforded.

(7) **Curative Inoculations with Cultures and Serum.**—E. Fränkel and Manchot have treated 57 cases of typhoid fever with a sterilized liquid derived from a culture of the bacillus of Eberth in thymus bouillon and heated to 140° F. (10 C.). Of this, $\frac{1}{2}$ c.cm. was injected deeply into the gluteal region, with favorable results.

In 1897 Bokenham³ prepared an antityphoid serum from the horse.

¹ *Med. News*, February 11, 1899.

² See *Therap. Gaz.*, April 15, 1900, by the writer.

³ *Transactions London Pathological Soc.*, vol. xlix., p. 373.

Chantemesse¹ has treated 1000 cases (using his own serum), with a death-rate of 4.3 per cent., while of 5121 patients who received routine treatment during the same period, 17 per cent. died. Hughes and Carter treated a number of cases with blood-serum derived from convalescent cases, but apart from a decided lowering of temperature the general course of the disease was not perceptibly modified. Jez² found that he was able to obtain from the organs of animals inoculated with typhoid bacilli substances capable of exercising protective and curative influences upon typhoid infection. This anti-typhoid extract was employed in the treatment of 18 cases of typhoid fever, being administered by the mouth in doses of from a teaspoonful to a tablespoonful every two hours, subcutaneous injections proving less serviceable. In the cases thus treated the characteristic temperature-curve was lost, the pyrexia becoming remittent and soon disappearing. M. W. Richardson,³ from a study of specific therapy in 130 cases of typhoid fever with Vaughan's non-toxic residue of the typhoid bacillus, concludes that it is apparently effective in the prevention of relapses if inoculations are continued into convalescence; they also seem to make the typhoid process longer, but milder. The value of vaccines for the following purposes must be conceded: "(1) As a means of prophylaxis; (2) in suitable cases when continued during convalescence, to prevent relapses; (3) to combat local infections with the typhoid bacillus, as, for example, bone suppurations which arise in the period of convalescence; and (4) for the removal of the typhoid bacilli from the feces and urine in the case of typhoid carriers."⁴

(8) **Treatment of Individual Symptoms and Complications.**—*Headache.*—Early in typhoid the headache demands relief. Absolute rest and cold to the head frequently suffice. Depressant analgesics are to be avoided so far as possible, although it sometimes becomes necessary to resort to them. At such times those least objectionable are to be selected. I have found that a mixture containing sodium bromid (gr. x to xv—0.6480 to 0.9720) and the deodorized tincture of opium (Mij to v—0.1998 to 0.3330) in each dose, given at intervals of three or four hours, exercises a striking palliative influence. In occasional instances the above mixture fails, and then phenacetin (gr. ij to iij—0.1296 to 0.1944) may be substituted for the opium in the same combination.

Insomnia.—The cold baths or other measures calculated to relieve the headache often procure for the patient refreshing sleep. It is important not to allow him to go too long without sleep, since this tends to the development of a pronounced "typhoid state" and its concomitants. When the agents recommended for the headache fail, I employ morphin hypodermically in small doses (gr. $\frac{1}{16}$ to $\frac{1}{8}$ —0.004 to 0.008) during the evening hours with excellent results, withdrawing the remedy so soon as decided amelioration of this symptom has taken place. Codein, sulfonal, and, more recently, veronal, trional, and chloralamid, have proved useful.

Chloral is certain in its action, but I have abandoned its use, since it apparently produced circulatory collapse in two instances.

Delirium.—Since the introduction of the Brand method delirium rarely calls for special medication. I have observed, in common with

¹ *Hyg. gen. et appliq.*, 1907, p. 577.

² *Wiener med. Wochen.*, Feb. 18, 1899, p. 345.

³ *Boston Medical and Surgical Journal*, Oct. 3, 1907.

⁴ *Journal of the American Medical Association*, Dec. 10, 1904, by the writer.

others, particularly during the advanced stages, that in cases in which the circulation was feeble and in which typhomania was a prominent feature, the administration of stimulants with a free hand completely dispelled the nervous phenomena. If alcohol fails, ether (\mathfrak{M}_x —0.666—at a dose) may be given hypodermically, and repeated in one or two hours if necessary. To combine with the arterial some nervous stimulant (musk, valerian) will be found serviceable, particularly in cases in which the delirium assumes an hysteric type. Of special value are the bromids, hyoscin hydrobromate, the persistent use of ice to the head, and the agents suggested for the headache and insomnia.

Vomiting is rarely troublesome. Its chief cause is the irritation of the gastric mucosa, from improper diet or medication. After the removal of the cause, the use of ice in small pieces by swallowing affords relief. If vomiting occur during the period of development, minute doses of calomel, combined with sodium bicarbonate, may be prescribed with good effect. If it occur during the fastigium, the amount of milk taken should be reduced by one-half, peptonized, and then diluted, preferably with lime-water. If the patient experience a strong aversion to milk, it must be suspended temporarily and albumin water and broths substituted. Dry champagne may be administered simultaneously. Excessive irritability of the stomach calls for rest of the organ for a period of twenty-four hours, the patient being meanwhile supported by rectal alimentation and subcutaneous medication.

Diarrhea more than any other single symptom claims special attention. Two to four movements daily do not constitute diarrhea and do not demand treatment. It may be caused by overfeeding or by improper food—as shown by the stools, as a rule—in which case regulation of the diet is curative. It is often due to ulcerated and catarrhal lesions of the intestines, and particularly the large. Unquestionably, intestinal antiseptics which possess the property of insolubility are most valuable. Astringents may be combined with the latter or given separately. The subjoined formulæ have yielded good results in my own hands:

$\mathfrak{R}j$. Betanaphtol, \mathfrak{zj} (4.0);
Bismuth. subgallat., $\mathfrak{z}ij$ (8.0).

\mathfrak{M} . et \mathfrak{ft} . capsulæ No. xxiv.

\mathfrak{Sig} . One every two or three hours.

Or,

$\mathfrak{R}j$. Plumbi acetat., \mathfrak{gr} . xxiv (1.555);
Phenylis salicylat., \mathfrak{zss} (2.0).

\mathfrak{M} . et \mathfrak{ft} . capsulæ No. xii.

\mathfrak{Sig} . One every three or four hours, as required.

Large doses of bismuth (\mathfrak{gr} . xxx—2.0) every third hour are useful.

Late in typhoid fever, when the ulcers are fully developed, opium is of service; it tends to arrest the peristaltic action which keeps up the diarrhea and favors the spread of the inflammation to the peritoneum. When distention is increased by the use of opium it is to be omitted. I have recently observed brilliant results from the use of rectal injections of an astringent solution (tannic acid 1–2 per cent.), alternated with an antiseptic solution (salicylic acid 1–2 per cent.), each given once daily.

Constipation, which is often present, particularly during the first week, is to be relieved by simple enemata of soapsuds every second day. Calomel may be used in the early stage of dynamic cases. Its employment may be followed by symptoms of a milder type than are ordinarily encountered. If constipation exists during the third week, accompanied by an oscillating temperature-curve, saline laxatives in small but repeated doses may cut short the attack.

Tympanites.—This is sometimes a most distressing symptom, and treatment should be commenced early. As a remedy for tympanites turpentine is excellent and richly deserves a trial, but it does not, as some claim, influence the general course of the disease. When employed for this symptom alone I prefer to apply it in the form of stupes over the abdomen, although when, as is frequently the case, the gases occupy chiefly the large bowel, turpentine enemata should be given. Irrigation of the colon with the normal saline infusion has recently proved most effective in relieving excessive tympanites. Eserine, gr. $\frac{1}{100}$, every third hour, administered hypodermically, sometimes proves efficient.

The meteorism is often increased by the milk taken, and a change of food to meat-juices and albumin-water may be tried.

Hemorrhages.—The bowel-movements, if the hemorrhage has been copious, must be allowed to pass into the draw-sheet. The ice-bag (suspended if possible) should be applied to the right iliac region, and ice freely given by the mouth. Morphine, to control peristalsis, must be given, and, by preference, hypodermically. It may be combined with full doses of the acetate of lead. Cases in which slight oozing appears from time to time require turpentine. Adrenalin chlorid is serviceable, and Curtin¹ derived advantage from the use of suprarenal extract in cases in which there was general hemorrhage. The amount of food should be greatly restricted, and in serious bleedings abstinence from food for from twelve hours to three or four days is to be observed. When feedings are resumed, a teaspoonful or two of cold milk (repeated every two hours) may be given during the first twelve hours, then gradually increased in amount. For severe hemorrhages, *saline infusion*, either by the method of intravenous injection or by hypodermoclysis or enteroclysis, is to be strongly advised. The saline solution not only raises the blood-pressure in the vessels, but it also has a hemostatic action. The proper strength is 8:1000, and from 10 c.c. (3 fluidrams) to one-half liter may be employed if the collapse is marked, and repeated several times in the course of a day. Rectal injections may be somewhat larger. McCrae² advises calcium lactate in doses of 20 grains a day; it may be given subcutaneously, if rapid action is desired, in a 1 per cent. solution. Calcium salts are indicated where the coagulation time is slow.

Peritonitis.—Operation for perforation offers some hope of cure, and with the progress of convalescence the chances of recovery from this accident improve. Deaver regards the acute development of pain and generalized abdominal rigidity and tenderness as an urgent indication for immediate celiotomy. Keen's statistics show that between twelve and twenty-four hours after perforation is the most favorable time for opera-

¹ *Proceedings Phila. Co. Med. Soc.*, Nov., 1902.

² *Jour. Amer. Med. Assoc.*, Sept. 19, 1908.

tion, this period giving 30 per cent. of recoveries. Le Conte¹ holds that it should be immediately undertaken. Rarely, appendicitis supervenes in typhoid fever. It demands prompt removal of the appendix. Peritonitis due to direct extension of the infectious inflammation of the bowel without perforation calls for saline purgatives.

Lobar Pneumonia.—Its treatment, when a complication, will be considered hereafter (*vide* Secondary Pneumonia). Pneumo-typhoid requires the same measures, until the true typhoid symptoms arise, as primary adynamic pneumonia (*vide* p. 126).

The *hypostatic congestion* of the lungs is to be met by heart-stimulants and by changing the position of the patient at frequent intervals.

Bronchitis.—No special measures are necessary when the bronchitis is confined to the larger tubes, as in typical cases, while, if diffuse, its management is like that of *broncho-pneumonia* (*vide* p. 557).

Laryngitis.—For this condition counter-irritation should be tried; and if this fails, a small blister may be applied below the angle of the jaw on either side. For edema of the larynx scarification and the inhalation of steam are useful measures. Then, should suffocation become imminent, tracheotomy should be performed without delay. Operation "gives a mortality of only 55.5 per cent." (Keen).

Bed-sores.—The preventive measures have already been considered, but the smallest bed-sore demands active treatment. It is to be kept clean and dusted with a powder composed of equal parts of boric acid, calomel, and bismuth; if sluggish, with a powder made up of aristol and iodoform.

Thrombosis of the femoral vein is best treated by elevating the part and keeping it at perfect rest. An ointment composed of equal parts of unguentum ichthyol (12 per cent.), lanolin, and unguentum belladonna, may be applied along the course of the affected vessel thrice daily.

(9) **Management of Convalescence.**—Some of the points connected with this subject have already been discussed (*diet, time for getting up, etc.*). I may add that should a recrudescence occur the patient should be kept at rest in the recumbent posture and a return made to the liquid forms of food. Often a moderate laxative serves a good purpose, particularly if an indiscretion in diet have been committed. The ulcers may not be healed, though the temperature may have been normal for a week or ten days; hence the patient should not be allowed to stir about for a period of two weeks after the temperature has returned to the normal. At first his movements should be slow; he may soon, however, be allowed to exercise gently in the open air during seasons of favorable weather. Mental excitement is to be avoided. Occasionally during convalescence the diarrhea persists, being due to colonic ulceration, and is best treated by restricting the diet to milk and other light forms of albuminous food. The patient must be confined to bed. Medicinal treatment by the oxid of zinc internally and the use of astringent and antiseptic rectal injections, as before indicated, usually proves successful. Constipation is best relieved by simple enemata. Most patients require tonics. We should begin with a vegetable salt of iron in combination with a simple bitter

¹ *Jour. Amer. Med. Assoc.*, Nov. 8, 1902.

(such as the infusion of gentian), and later an inorganic salt of iron, with quinin and strychnin, may be resorted to. If there be a predisposition to tuberculosis, cod-liver oil and creasote should be given for a period of two or three months. Relapses are to be treated as primary attacks.

PARATYPHOID FEVERS.

This term is applied to a group of affections that closely simulate typhoid fever clinically, but are due to different microbic cause.

Pathology.—The anatomic changes are simply those of septicemia with splenic swelling and occasionally non-specific ulcers in the intestine. H. G. Wells and L. O. Scott¹ have summarized the pathologic findings of 5 cases of paratyphoid and concluded that its pathology is different from that of ordinary typhoid. In 3 cases reported the ulcers resemble those of dysentery rather than those of typhoid; there are slight, if any, changes in Peyer's patches or the solitary follicles. The mesenteric glands show alterations, and focal necroses have been noted in the liver.

Etiology.—The disease is not a unit, but is probably caused by several members of the colon family. These organisms possess properties intermediate between the bacillus typhosus and the bacillus coli communis. Longcope² and others have found the paracolon bacillus; Ruxton, the paratyphoid bacillus, which is closely related to the bacillus typhosus. The *predisposing factors and sources of infection* are about the same as for true typhoid fever. Sacquépée and Bellot traced an epidemic comprising 19 cases to a cook (paratyphoid carrier). Minertz³ claims paratyphoid to be an entirely different disease from typhoid, his experience confirming the fact that infection is derived from meat, especially pork, and not from human sources.

Symptoms and Course.—Typical cases usually manifest features that should arouse suspicion of their true nature. Brill has contrasted the diagnostic features of true typhoid fever and these allied conditions.

The incubation-period is somewhat briefer and the onset more abrupt than that of true typhoid. After three or four days of malaise the temperature rapidly rises to 104° F. (40° C.) or over, replacing the characteristic step-ladder curve. Mental dulness and apathy develop earlier and are marked. The initial headache is more intense, and constipation is common, although diarrhea is also observed. Brion's figures show diarrhea in 18 per cent. of the cases and melena in 5 per cent. The spleen is enlarged and rose-colored spots are prone to appear, but the Widal reaction is absent. The duration of paratyphoid fever may be short, and the temperature decline by rapid lysis or crisis, or it may be long. Convalescence is also less protracted. J. H. Pratt refers to the frequency of complications (4 per cent.); they differ but little, either as to incidence or character, from those of typhoid fever. Relapses may occur.

Diagnosis.—A bacteriologic diagnosis is essential. Cultures of paratyphoid bacilli can be obtained from the feces, urine, rose-spots, although preferably from the blood of the veins. The various subtypes of paratyphoid bacillus may be distinguished from one another by agglutination (Bielyaëff). It is necessary to test simultaneously the action

¹ *The Journal of Infectious Diseases*, I., No. 1, Jan., 1904.

² *Amer. Jour. Med. Sci.*, Aug., 1902.

³ *Medizinische Klinik*, Berlin, Sept. 25, 1910.

of serum upon the typhoid bacillus and upon the paratyphoid bacillus obtained from the patient. Swan¹ suggests that if a blood-culture is sterile, or if it is impossible to make such a culture, the patient should be catheterized under aseptic conditions and his urine examined bacteriologically. The paracolon bacillus may thus be obtained. Lessieur and Fischer state that the diagnosis should be based on an examination of the blood, as the agglutination test is frequently misleading.

Prognosis.—The course is usually favorable, although a few fatal cases have been reported.

The **treatment** does not differ from that of true typhoid fever.

TYPHUS FEVER.

(*Ship-fever, Camp-fever, Jail-fever, etc.*)

Definition.—An acute contagious disease of unknown specific etiology. It is characterized frequently by an abrupt invasion, and is marked by rigor, high fever, early nervous symptoms of great prominence, a maculo-petechial eruption appearing between the third and fifth days, and a termination by crisis.

Historic Note.—In 1759 the name *typhus*, which is at present universally employed, was given to it by Sauvages. In pre-sanitary times it prevailed in epidemic and endemic forms, particularly in Ireland and Russia, and its devastations among the armies were more destructive of human life than even shot and shell.

In 1812 typhus fever first appeared in America in the New England States. Its ravages did not cease until every Eastern State had been visited by the plague, when it totally disappeared. In 1836 it reappeared in Philadelphia, and with deadly effect. Since then the disease has not gained a foothold on our shores, although in the early part of 1893 it appeared in New York City, and 150 cases resulted.

Pathology.—After death the eruption continues to be visible. Rigor mortis is often delayed.

Certain organs may present pathologic appearances, but they are not constant and are the result of the secondary infection which the typhus invites. The serous membranes are the seat of ecchymoses. There is hyperplasia of the lymph-follicles, but no subsequent ulceration. The muscles are dark and often show hyaline and granular changes; the *heart-muscle* is especially apt to undergo a granular degeneration. The *spleen* is considerably enlarged, soft (even diffuent at times), and of a dark (frequently bluish) red color. The *liver* is somewhat swollen and may be softened; the *kidneys* may manifest the changes belonging to nephritis or mere congestion. In the *lungs* are found a variety of lesions peculiar to different complicating conditions (bronchitis, lobular pneumonia, lobar pneumonia, pulmonary congestion, edema), and occasionally *pleurisy* (serofibrinous or purulent) may be present. *Nervous lesions* are conspicuous by their absence. Commonly there is *cerebral congestion*. *Meningitis*, however, is rare. The *blood-changes* are marked, the color being dark, the fluidity much increased, while the coagulability is greatly diminished.

¹ *Amer. Jour. Med. Sci.*, May, 1906.

Etiology.—The direct cause or special micro-organism connected with the typhus contagion has not, as yet, been isolated, notwithstanding the fact that the morphologic and biologic studies of the blood obtained by Brannan and Cheesman from the finger-tips of six patients during the mild epidemic of typhus in 1893 showed the presence of a bacillus that proved pathogenic for rabbits, guinea-pigs, and white mice.¹ Lewaschew² has also detected in the blood of typhus patients a distinctive micro-organism.

It is a known fact, nevertheless, that when typhus arises in a locality in which it was previously unknown it is dependent upon a transference of the typhus virus from without, and does not arise spontaneously. The different *modes of conveyance of this poison* are imperfectly known; it may leave the body in the expired air, in the epithelial scales thrown off, and in other excretory or secretory products. The poison is transmitted by *contagion* from the patient to others who approach him; and it may be transferred by means of *fomites* (wearing apparel, articles of furniture, etc.). Littlejohn³ reports an epidemic, and states that only those in intimate contact with the sick appear to become infected. The precise *gateway* into the body is not known, but the virus is more likely to enter through the respiratory tract (by inhalation) than through the alimentary canal.

Predisposing Causes.—The influence of *insanitary surroundings* upon the spread of this affection is positive and vital. Among special conditions may be mentioned filth, poverty, famine, and overcrowding, and hence it may be inferred that typhus is a disease of the lower classes. It prevails in jails and camps. Among additional etiologic influences are overwork, intemperance, and depressing emotions.

Age.—The young and middle aged furnish a preponderant proportion of cases, owing to the fact that they are more liable to exposure to the virus than during other periods of life. *Sex* has no influence, and the *season* plays only a minor part. Epidemics, however, occur oftenest in winter, since the homes of the underfed pauper population are illy ventilated, and hence favor concentration of the specific poison. It almost invariably prevails in an epidemic form.

Clinical History.—**Incubation.**—This lasts from nine to twelve days. There may be prodromal symptoms during the concluding days of this period, such as anorexia, general malaise, etc., but in most instances *invasion* is sudden.

Pre-eruptive Stage.—The *early* symptoms are either a series of chills or one severe rigor, accompanied by vertigo, tinnitus, headache, muscular pains, profound prostration, and fever. The *temperature* quickly ascends to a high level, reaching 104° or 105° F. (40° or 40.5° C.) as early as the second or third day. The fever is continuous in type, and in severe cases a serious systemic condition may often be developed. The *pulse* is accelerated proportionately to the temperature and is of good volume. Bronchitis may be present, the appetite is lost, and the thirst is excessive, while a thick, yellowish-white coating covers the tongue. *Vomiting* occurs, and may be a prominent symptom. The *urine* is often scanty, its specific gravity is increased, and it may contain a trace of albumin. The cheeks are flushed and the eyes are injected.

¹ *Annual of the Universal Medical Sciences*, 1893, p. 60, section H.

² *Ibid.*, p. 61, section H.

³ *Public Health*, Sept., 1899.

Nervous symptoms appear early—often at the very onset—and are quite pronounced. At first there may be either mild or active delirium, but soon there is stupor or even coma, and the face takes on a dull, stupid, besotted appearance. The spleen is generally enlarged.

Eruptive Stage.—Between the third and fifth days of the invasion the *characteristic eruption* appears *without an accompanying decline in the temperature*. The rash comes out first upon the trunk (chest and abdomen), extending thence over the rest of the body, but, strangely enough, often sparing the face. The crimson-red maculæ are changed in two or three days to a darker hue (petechiæ), and when coalescence occurs we have the spotted effect that has caused the name of *spotted fever* to be given to it. This name is also given to cerebro-spinal meningitis, in which the eruption, however, does not appear at any given time and is extremely inconstant. Not all of the maculæ are converted, but some may remain as rose-spots, particularly in mild forms of typhus, and these disappear when pressed upon, while the petechiæ do not. The skin-surface between the spots is sometimes diffusely hyperemic, and the eruption is usually rather abundant, though in well-authenticated cases it has been scanty or even wholly missing. The skin may also present darker and lighter blotches, producing a mottled appearance. In the stage of eruption the symptoms become aggravated in typical and severe cases. The temperature continues high, often reaching 106° F. (41.1° C.) or even higher, with slight nocturnal remissions. The pulse becomes quite rapid (120–140 or more), feeble, sometimes dichrotic, and irregular, and the respirations increase markedly in frequency. At this time severe bronchitis, leading to *broncho-pneumonia*, is apt to occur as a complication. The *tongue* is brown, fissured, tremulous, and occasionally black and rolled up, without power to protrude from the mouth. Sordes form on the teeth and lips. The *urine* is scanty, high-colored, and often albuminous.

The *nervous disturbance* is intense, and may take the form of typhomania, leading to complete coma or maniacal delirium. The patient often lies with eyes open, staring into space, yet unconscious (*coma-vigil*). The motor nerves show derangement (tremors, subsultus tendinum), and carphologia (picking at the bed-clothes) is a common symptom. The decubitus is dorsal; the flushed cheeks become dusky, the face expressionless, and the pupils often contracted. The prostration reaches an extreme degree, and absolute exhaustion often terminates life.

As a rule, in favorable cases the end of the febrile period comes by *crisis* between the fourteenth and seventeenth days of the disease. Immediately preceding the crisis there is generally a sudden rise of the temperature (*perturbatio critica*), and the decline may be interrupted by slight exacerbations. The occurrence of the crisis is marked by rapid improvement in the symptoms. The mind becomes clear (sometimes following a profound sleep), the eruption fades quickly, the facial phenomena disappear in inverse order of their appearance.

Leading Symptoms and Complications.—Course of the Fever.—Although the temperature rises rapidly on the first day of the illness—the highest grade is usually reached as late as the fifth or sixth day. Hyperpyrexia usually heralds a fatal termination, the temperature mounting to 108°,

109° F. (42.7° C.), or higher, though in light cases the acme may not exceed 103° F. (39.4° C.). The temperature pursues the continued type and ends by crisis. Occasionally the fever declines by rapid lysis. About the beginning of the second week the patient emits a disagreeable odor that is regarded as characteristic by some writers.

The **lungs** frequently present complications (*vide* Pathology), among which are *bronchitis*, *broncho-pneumonia*, and *hypostatic congestion*. Broncho-pneumonia is dangerous, its development often preceding a fatal termination, and it may lead to pulmonary gangrene and empyema. Sero-fibrinous pleurisy and lobar pneumonia also occur as complications, and to recognize the latter the physical signs must be appreciated, the rational symptoms being in abeyance.

The **heart** in typhus continues to grow progressively weaker until, in many cases, a fatal issue is reached. This is manifested by the change in the character of the first sound. A systolic *murmur* (probably of hemic origin) may be audible at the apex.

The **nervous phenomena** have been sufficiently detailed. *Meningitis* has been met with, but is rare as a complication. *Hemorrhagic nephritis* rarely supervenes. During the febrile period the uric acid and urea increase in quantity, while the chlorids decrease.

The **digestive tract** rarely presents distressing symptoms and complications. *Hematemesis* is most common, and *cancrum oris* has been noted occasionally. Cases in which the mouth does not receive proper care are apt to develop *parotitis*, which often passes on to suppuration, and *septic processes*, causing abscesses in different parts of the body (joints, subcutaneous tissue), may arise as complicating events.

Among the **sequelæ**, *neuritis*, followed by *paralyses*, deserves first place, and *gangrene of the extremities* (toes, fingers) has been observed.

The **general course and duration** of typhus are variable. There is a *mild type* whose course is run in from seven to ten days, and in such the crisis occurs soon after the appearance of the eruption. In this type the development of serious symptoms or grave complications is the exception. A *malignant type*, however, also occurs (*typhus siderans*), and this often proves fatal before the time for the appearance of the rash.

Some epidemics are characterized by the relative frequency of light forms, and others by the severer types of the disease.

Diagnosis.—On the known presence of an epidemic, the special causative factors (unhygienic surroundings, exposure to the poison) and the course and characteristic symptoms, the diagnosis of typhus fever can be made. Of special value is the eruption—its time of appearance (third to fifth day), mode of distribution, and petechial character. The recognition of lighter types, on the one hand, and malignant, on the other, is not possible from the symptoms alone, but here a knowledge of the existence of an epidemic in the vicinity is often helpful.

Differential Diagnosis.—*Cerebro-spinal meningitis* may be distinguished by a more intense headache, by retraction of the head, hyperesthesia, intolerance of sounds, photophobia, palsies of the eye-muscles (*strabismus*), a tendency to convulsions, and by both the absence of the typhus eruption and the expressionless countenance. Quincke's lumbar puncture may be practised.

Uremia is excluded by the previous history, the vomiting, headache,

convulsions, coma, and by the absence of the high temperature and petechial eruption of typhus. Characteristic urinary phenomena are associated in uremia, and rarely *acute hemorrhagic nephritis*.

The eruption of *malignant measles* may bear a close resemblance to that of typhus; the rash in typhus, however, appears first upon the trunk, that of measles, upon the face. Koplik's spots do not appear in typhus. Points connected with the epidemicity of measles, as the occurrence of mild and typical cases, must be taken into account. *Typhoid fever* is readily differentiated from typhus (*vide* p. 48). Typhus fever must also be distinguished from *Rocky Mountain Spotted Fever* (*vide* p. 327).

Relapses are among the rarest of clinical events, and one attack, as a rule, bestows immunity for life.

Prognosis.—To arrive at a correct prognosis it is necessary to consider (1) the degree of severity of the particular type from which the patient is suffering, (2) the number and character of the complicating conditions present, and (3) circumstances connected with the individual, among which his food-supply and sanitary surroundings are to be recollected. Improved sanitation has reduced both the incidence and mortality-rate, which is now between 10 and 20 per cent.

Treatment.—This embraces, in the main, the same principles that were found to govern the treatment of typhoid fever.

Prophylaxis demands *thorough disinfection* and *absolute isolation*. A special hospital for contagious diseases is always to be preferred to the best accommodations obtainable in private families. When, however, patients cannot be transferred to special hospital wards the sick-room must be kept clean, well ventilated, and at a temperature ranging from 60° to 65° F. (15.5° to 18.3° C.). No one other than the doctor and nurse should be allowed to occupy or even enter the room. The thorough disinfection already described under Typhoid Fever must be enforced, and the importance of supplying fresh air to typhus patients, as emphasized long since by Alonzo Clark, has been abundantly shown by the great reduction of the mortality-rate among those treated in tents as compared with that in the hospital wards.

The **general management**, including the use of stimulants, in this disease does not differ from that advised in typhoid fever. Fresh water should be given freely at regular intervals. *Hydrotherapy* constitutes the best means at our command for controlling the temperature and the nervous symptoms. In addition, the use of antiseptic agents and tonic measures are to be recommended. The fact that typhus is a self-limiting affection gives those measures that are intended to combat exhaustion, and especially heart weakness, first rank in the treatment of this affection. Strychnin (gr. $\frac{1}{40}$ —0.0015) and camphor in sterilized oil (gr. ij—0.13); one or both may be given hypodermically every third hour if there be failure of the circulation.

DYSENTERY.

Definition.—An infectious inflammatory disease of the large intestine, characterized anatomically by ulceration of the intestinal mucosa, and clinically by frequent mucous and bloody discharges, tenesmus, fever and prostration becoming profound. It is a truly epidemic disease, yet it also occurs constantly in endemic form, and particularly is this true of temperate climates.

Varieties.—Etiologically considered, two varieties are recognized: (1) bacillary and (2) amebic. Under bacillary dysentery a description of the sporadic form (catarrhal dysentery) will be given.

Historic Note.—Few diseases have been longer known than dysentery, of which we have a description by Hippocrates. Galen localized the chief seat of the affection in the colon, and in 1626, Sennertus defined its sporadic and epidemic character and some of its leading clinical features. To Morgagni belongs the credit of having made the first postmortem anatomic study of the disease. Further and more accurate pathologic contributions were made in the earlier part of the present century by Cruveilhier and Rokitansky, and, more recently still, the whole subject of the morbid anatomy of this disease has been carefully investigated by Virchow, whose results have settled most of the questions connected with the subject. In the United States dysentery has prevailed epidemically upward of a century, the time of greatest prevalence in different districts having been about the middle part of the present century (1847–55). Woodward has given us the only complete record of the various outbreaks in this country, and an account of the ravages of dysentery in both armies during the War of the Rebellion is given in his *Report*, which records 259,071 cases of acute and 28,451 of chronic dysentery. The disease is far less frequent than formerly, owing to the advance made in recent times in sanitary science.

Etiology.—A few general considerations, having reference to the causation of the different forms in common, may be adduced here.

Among **predisposing factors**, *season* heads the list, dysentery being most common in the summer and autumn; great and sudden changes of temperature are more potent than equal changes in humidity. *Climate* has a marked effect, and high temperature must be regarded as a powerful agency, since the disease is much more prevalent in warm than in cold climates, though it is met with in epidemic form as far north as Norway. *Malarial districts* suffer more than non-malarial. *Unhygienic conditions*, as shown by the local epidemic outbreaks in armies, jails, barracks, institutions, etc., predispose to the affection.

Among factors connected with the individual are: (*a*) *Catarrhal* conditions of the intestinal tract, particularly if this be caused by unripe fruit or other unwholesome forms of food; (*b*) *Age*. Although no age enjoys immunity against dysentery, most cases are met with in adults under thirty-five years. *Sex* and *race* are probably without appreciable influence.

(1) BACILLARY DYSENTERY.

(*Acute Dysentery.*)

This term is appropriately applied to the usual acute epidemic form of the disease. I shall describe here two clinical types: (*a*) catarrhal

dysentery and (b) diphtheritic. It is probable, but not proved, that all of the cases of bacillary dysentery are due to a common micro-organism—the Shiga bacillus (*Bacillus dysenteriae*).

The classification of catarrhal dysentery, therefore, still rests upon its clinical and pathologic manifestations, although many, if not all, of the cases as shown by the observations of Vedder and Duval¹ are etiologically identical with epidemic tropical dysentery. Flexner's statistical studies indicate that the *Bacillus dysenteriae* (especially the so-called "Flexner-Harris" type), can be isolated from the intestinal discharges, and the intestinal mucosa of "a large percentage of children suffering from the diarrheal diseases prevailing along the Atlantic sea-board of the United States during the summer months."²

(a) CATARRHAL DYSENTERY.

(*Sporadic Dysentery.*)

Pathology.—The solitary follicles are affected chiefly, and are the seat of hyperplasia, followed by necrosis, with the formation of small ulcers. This is common in children. There may be a purulent inflammation of the entire mucosa, with more or less erosion of the surface, and superficial ulceration exists. In both forms the lesions are mainly confined to the large intestine, though the ileum is sometimes implicated.

Special Etiology.—The catarrhal form of the disease is the one most commonly met in the United States, and is to be classed with acute dysentery; it may accompany some of the acute infections (scarlatina, malaria, typhoid fever, tuberculosis), and is seen in institutions.

Clinical History.—There may be *prodromes*, lasting one or two days, which take the form of a mild gastro-intestinal disorder (anorexia, slight pains in the abdomen, followed by diarrhea).

The *characteristic symptoms* are mild colicky pains in the abdomen, followed by discharges from the bowel, which at first number from three to six daily. Soon they become frequent and are accompanied by straining and tenesmus, and now their number ranges from ten to no less than one hundred or more per day. Indeed, the desire to go to stool may be almost constant, and the rectum is the seat of intense burning sensations during and after each evacuation of the bowel. The character of the discharges varies with the different periods of the affection. During the first thirty-six or forty-eight hours they are feculent (sometimes scybalous masses), rather copious, and intermingled with some mucus and blood. For the next four or five days the stools are scanty, measuring from 2 drams (8.0) to $\frac{1}{2}$ ounce (16.0), and are made up of a sero-mucous fluid or of a muco-purulent material with blood. The chief constituents of the stools are mucus, blood, and pus, any one of which may preponderate.

Microscopic examination of the usually glairy stools shows red blood-corpuscles, numerous leukocytes, generally large, oval or round epithelioid cells containing fat-globules, vacuoles, and bacteria (especially those connected with putrefaction).

A few shreds (portions of necrosed mucous membrane) may appear

¹ *Jour. Exper. Med.*, Feb. 5, 1902.

² *Studies from the Rockefeller Institute for Medical Research.* Reprints, vol. ii., 1904, p. 134.

from time to time in the dejecta. At the close of the first week, and a little later, the discharges become less frequent and the amount of mucus and blood diminishes. The stools are now of a greasy brown or dark-green appearance, fecal matter reappearing in them, and soon they are again fully formed.

Other Symptoms Referable to the Alimentary Tract.—The tongue has a greasy coating—moist at first, dry later—and at last may become red and glazed. Anorexia is present, with excessive thirst, and vomiting may rarely occur. There will usually be tenderness over the line of the colon, but there is an absence of tympanites.

The *general symptoms* are well marked only in the severer types. The patient is debilitated, sometimes even collapsed, as shown by the small, frequent pulse, cool skin-surface, the rapid wasting, and weak, hoarse voice. The temperature is not much elevated, though it may touch 103° or 104° F. (39° or 40° C.), and the curve is an irregularly remittent one.

Diagnosis.—This can easily be made upon the intestinal features and from the character of the stools—frequent, small, slimy (or bloody) discharges, accompanied by distressing tenesmus.

Differential Diagnosis.—Symptoms simulating dysentery may appear in the course of certain rectal affections, such as *strangulated hemorrhoids*, *syphilis*, and *epithelioma*. In these conditions there is a different history and the symptoms of proctitis are less acute, while a physical examination of the rectum will settle the diagnosis in doubtful cases.

Prognosis.—The *duration* of mild cases is from eight to ten days, and in severe types from three to four weeks. The *prognosis* varies according to the type of the affection; but commonly this is not aggravated and recovery is to be expected. Occasionally, however, the disease is threatening to life. Serious nervous symptoms (delirium followed by coma) may develop and cause a fatal termination. When death occurs it is usually due to exhaustion, and is seen particularly in persons previously enfeebled by disease or in the very young and the aged. Complications influencing the prognosis are exceptional. This variety probably does not occur in extensive epidemics; but it prevails in tropical and sub-tropical countries, and also throughout Europe and North America.

(b) DIPHTHERITIC DYSENTERY.

(*Acute Tropical Dysentery.*)

Definition.—An intestinal inflammation (usually colonic), accompanied by a croupous, or true, diphtheritic exudation. It is epidemic in Japan, but prevails wherever large numbers of persons are closely associated, as in armies, asylums for the insane, ships, and the like.

Pathology.—In mild grades a grayish-yellow, croupous exudate appears upon the inflamed mucosa, with a necrosis of the epithelial layer that is often limited to the top surface of the folds of the colon. In other instances the diphtheritic infiltration involves all the layers of the bowel, which now becomes greatly enlarged, its mucous membrane being converted into a yellowish-brown, thick, elastic mass, sometimes extending along the entire length of the large intestine. The changes may be confined to the circumscribed areas (flexures of the colon and

rectum), and thick sloughs may be cast off, leaving behind ulcers of corresponding size and depth. The morbid changes in some cases are principally ulcerative in character, simulating those described under Catarrhal Dysentery (*vide* p. 73). Indeed, the pathologic unity of the various forms of bacillary dysentery would appear to be almost established.

Bacteriology.—The distinctive pathogenic agent is the *Bacillus dysenteriae* discovered by Shiga¹ during his investigations into Japanese dysentery. Flexner found the same organism. Duval, Harris, and Flexner have described different races of the *Bacillus dysenteriae*, showing that decisive criteria of difference are observable, which separate this organism from the *Bacillus typhosus*. The *Bacillus dysenteriae* is not normally found in the intestines. The Shiga bacillus, however, "is inactive to blood-serum from typhoid cases, but reacts with serum from dysenteric cases to which bacillus typhosus does not respond" (Flexner). It may be that a number of bacilli which closely resemble one another, yet different, are capable of causing epidemics of true dysentery. Pfuhl² found dysentery bacilli in the intestines of soldiers returned from China one year after the initial attack; this persistence may have a bearing on the geographic distribution of bacillary dysentery and its spread in the United States since the Spanish-American war.

Mode of Conveyance.—Messrs. Ryder, Richards, Peabody, Canavan, and Southard studied an institutional epidemic in which the first case was probably an introduced probable carrier; they believe that the epidemic was due to flies, and that occasional cases of dysentery depend mainly on contact-infection with the products of intramural carriers.

Clinical History.—The affection usually has an *acute onset*, and one characterized by an appearance simultaneously of severe local and general symptoms. There may be an initial *chill*, and there is *fever*, which rises rapidly, together with a marked and early appearing prostration and delirium. The fever-curve is of the irregularly remittent type and its range is somewhat higher than in the catarrhal form of the disease. The pulse is greatly accelerated and tends to become erratic both as to rhythm and volume. Active delirium is common and may alternate with or merge into coma. Severe abdominal *pains* are complained of, and the discharges may be numerous, containing shreds and large sloughs, or even tubular pieces, of false membrane. When these elements are present in the stools, the latter are of a dark-brown color, emitting a fetid odor, and generally containing more or less blood and mucus. The dejecta are more hemorrhagic, as a rule, than in the simple, catarrhal variety. *Tenesmus* may be intense. There is an absence of polynuclear leukocytosis in this disease.

The **physical signs** are often prominent. The belly in most instances is greatly distended, and on pressure very tender—signs due to the fact that the lesions are situated chiefly in the large bowel.

The **diagnosis** rests upon the intestinal symptoms and the character of the dejections, associated with a grave general condition suddenly developed. As accessory factors to the recognition of this variety are the finding of the false membrane in the dejecta, and the appearance of the cases in an epidemic form. An absolute diagnosis demands either the isolation of dysentery bacilli from the dejecta (which, however, are

¹ *Centralbl. f. Bakt. u. Parasitenk.*, 1898, xxiv., Nos. 22–24.

² *Münch. med. Wochen.*, Feb. 11, 1902.

rarely present in mild cases and during the first days of the disease) or the agglutination reaction of the blood-serum, and this serves to differentiate bacillary dysentery from allied maladies, including typhoid fever.

Complications.—These are both numerous and varied, and include perforation of the gut followed by peritonitis, either localized or generalized (according to its seat); also pleurisy, endocarditis, pericarditis, parotitis, “anasarca, phlebitis, and nephritis” (Rumford). Hepatic abscess is never observed (Shiga).

The **prognosis** is almost wholly unfavorable. The principal element of danger is the profound toxemia, which rapidly leads to fatal asthenia in cases in which the stools consist of a blackish fluid with a horribly fetid odor and of bits of gangrenous masses (Duncan). Shiga states that the toxemia is most marked in cases in which the lesions are located high up in the intestine, and that the disease is most fatal in winter. The numerous complications also exercise a lethal tendency. Occasionally recovery follows, though more frequently the disease takes on a chronic course.

SECONDARY DIPHThERITIC DYSENTERY.

Here the lesions are similar in kind, but less intense, as a rule, than those of the primary form. This variety is met with as a terminal condition in not a few acute and chronic diseases; it often occurs in pneumonia (Bristowe), and less commonly in typhoid fever. Among chronic affections, upon which this condition may become engrafted, are nephritis, organic disease of the heart, and pulmonary tuberculosis.

No characteristic *symptoms* attend upon its invasion. There may be slight diarrhea—two or four liquid stools daily—but it is not often accompanied by tormina and tenesmus, and the discharges rarely contain any noticeable amount of blood, mucus, or shreds of pseudo-membrane. Secondary diphtheritic dysentery often induces fatal asthenia.

Sequelæ of Bacillary Dysentery.—In all forms a relapse is likely to occur, each attack increasing the liability of the patient to subsequent ones. Moreover, in persons who have recovered from acute dysentery we often observe a disordered digestion and irritability of the bowels. Rarely, chronic nephritis follows dysentery. The most interesting sequel, however, is paralysis, which occurs mainly in the form of paraplegia (S. Weir Mitchell). Stricture of the bowel is rare.

Treatment.—**Prophylaxis.**—This embraces isolation and a thorough disinfection of the discharges, which contain the specific germ of the disease, as soon as passed. The drinking-water during the epidemic prevalence of dysentery should be thoroughly boiled, and healthy persons should avoid cathartics, the use of improper food, or such as stimulates intestinal peristalsis, while an unhygienic environment (overcrowding, etc.) is to be corrected as far as possible. Shiga recommends that the dead bacillus emulsion (heated at 60° C. for thirty minutes) and a specific immune serum be injected simultaneously. One injection produces active immunity and the author tested the method on about 10,000 men in the district of Japan “where epidemic dysentery prevails most seriously, and was able to diminish the mortality in the district from 20 to 30 per cent. to about zero.” All sufferers from dysentery must be kept in bed, and should occupy a well-aired apartment.

The **diet** should consist of milk, whey, and light animal broths during the period of active intestinal symptoms. The blandest articles only

are either acceptable to the stomach or allowable in the diphtheritic variety, as Mellin's food (especially for children), egg-white, and zoolak, in small portions. During convalescence a return to the usual dietary is gradually to be made. All food should be given lukewarm.

Alcoholic Stimulants.—With the development of asthenia and cardiac failure stimulants must be employed, as in other acute infectious diseases. Diphtheritic dysentery calls from the very outset for free stimulation. The diffusible stimulants (*e. g.*, champagne) are often invaluable. Strychnin and digitalis (hypodermatically) may be required.

Medicinal Treatment.—If scybalous masses be passing, a dose of castor oil should be administered. It is well to convert dysentery into diarrhea. Measures to deplete the mucosa of the intestine and at the same time inhibit undue peristalsis are most effective, as magnesium sulphate. Dram doses may be given every hour or two, until the stools contain fecal matter and no more blood or mucus. In the later stages purgatives are attended with baneful effect.

Ipecacuanha has long been, and still is, regarded as possessing a specific influence in cases of dysentery. Its administration is usually preceded by a dose of opium (laudanum or morphin) which is given when the stomach has been empty for a few hours. Most authors recommend that large doses—gr. xx to ʒj (1.29 to 4.0)—should be administered; but it is probable that a small dose—gr. $\frac{1}{6}$ to $\frac{1}{4}$ (0.010 to 0.016) every half hour—is quite as effective; and in children the smaller doses are to be preferred and will be found to be quite efficacious. Other remedies should also be employed, and among these opium is particularly beneficial in combination with ipecacuanha or in the form of Dover's powder, which contains both agencies. Three chief symptomatic indications are met by the opium—pain, restlessness, and undue peristalsis—and to obtain the best effects from the opiate it should be administered in the form of morphin hypodermically. In cases in which tenesmus is an unusually distressing feature an opium suppository (gr. ij—0.1296) or laudanum (℥xxx—2.0, by enema) exercises a beneficial effect. Bismuth in full doses is useful (ʒss—j—2.0–4.0 every two hours), and I have frequently found the combined use of Dover powder, bismuth subnitrate, and salol of signal service. Cunningham, Stengel, and others have reported curative effects from the employment of sulphur; and Richmann prescribes the following powder:

| | |
|-----------------------------------|------------------|
| R. Sulphur sublimat., | gr. xvij (1.20); |
| Pulv. Doveri, | gr. v (0.33). |
| M. ft. chart. No. i. | |
| S. To be taken every fourth hour. | |

Antiseptic substances by the mouth for the purpose of disinfecting the intestinal canal and favoring the healing of the ulcerated surfaces after the removal of the necrotic pseudo-membrane, such as benzonaphtol (gr. xl–lx—2.592–3.788—in the twenty-four hours in divided doses), salol, opium, and silver nitrate are among the remedies of choice. The naphtol preparations being insoluble should be given in capsule and the silver nitrate in pill form one hour after food. Iodoform in a pill or capsule in doses of $\frac{1}{2}$ to 3 grains (.032 to .194 gm.) has been much lauded. Bose and Vedel employed in 4 cases intravenous injections of sodium chlorid, 7:1000 being the maximum strength.

The injections should be made early, and repeated, so that they will develop sustained general reaction and a modification of the general condition which can lead to recovery. Care should be taken as to the quantity used and the rapidity with which it is injected ($\frac{1}{2}$ to 3 ounces each minute should not be exceeded). Kendall advises dextrose infusions (25 per cent.) in normal saline solution; this tends to restore the normal dextrose.

Antiseptic irrigation of the bowel would be, if properly carried out, a curative measure, since by this means we may destroy the distinct micro-organisms. Unfortunately, the bowel is frequently so irritable as to seriously interfere with this mode of medication. Preliminary to their use we may also employ cocain in the form of a suppository, or a small quantity of a solution of cocain (4 per cent.), or a laudanum enema (Mxxx—2.0, in starch-water), after which a large injection may be tolerated if administered slowly and the flow be interrupted at intervals. Among the best agents are silver nitrate (gr. ss-j—0.032–0.064—ad $\bar{3}$ j—32.0), tannic acid (1 to 2 per cent.), salicylic acid (1 to 2 per cent.), and mercuric chlorid (1 : 6000). I have for a number of years been in the habit of employing these astringent and antiseptic solutions alternately, administering each once daily. Kuzmitzky,¹ MacDonald, and others have obtained good results with rectal injections of a tepid solution of potassium permanganate (1 : 4000) twice daily. The temperature of the water should, at first, range from 100° to 110° F. (37.7° to 43.3° C.), and subsequently this may be reduced. The patient during the administration of the enemata should assume the dorsal position, with the hips well elevated, and he should be turned from side to side during the injections. The existence of great irritability of the bowel may be met by using two catheters side by side, one of them serving as an outflow. Kruse² has produced a serum and has treated 100 cases with 8 deaths. Shiga has also discovered a serum of which he injects one dose of 10 c.c. in mild cases. In cases of medium severity, a second dose of 10 c.c. is injected after from six to ten hours, while in severe cases, a daily dose of 20 c.c. is repeated for two or three days. The mortality of dysentery under the use of this serum is reduced to less than one-half from that obtained from medical treatment.

Local means, in the form of hot fomentations, light poultices, and turpentine stupes, often afford much comfort. The various complications must be met by appropriate treatment, as under other circumstances.

CHRONIC DYSENTERY.

This form of the disease almost always succeeds an acute attack.

Pathology.—In most instances the large intestine is still the seat of ulceration. Some of the ulcers show no signs of healing; in others this process is going on; while in still others it is completed and puckered cicatrices are presented. The ulcers are deeply pigmented, as is the un ulcerated mucosa, which often presents a slate-gray or blackish color. The submucous and muscular coats are hypertrophied, as a rule, with occasional narrowing of the lumen of the bowel, and cystic degeneration of the intestinal glands is sometimes observed. In a small percentage of the cases ulceration does not occur, the mucosa presenting an uneven, puckered aspect, due to deposits of fibrous tissue.

Symptoms and Diagnosis.—Many of the most characteristic fea-

¹ *Woenno. Med. Jour.*, Nov., 1902.

² *Deutsch. Med. Woch.*, Jan. 1 and 15, 1903.

tures of the acute form are either but feebly expressed or altogether wanting. This is particularly true of the tormina and tenesmus. Certain elements found in the stools of the acute type (blood, shreds of pseudo-membrane, and tissue) are also rarely present. True *dysenteric symptoms*, however, may arise during acute exacerbations, with or without pain or tenesmus; then from three or four to a dozen or more fluid *dejections* are passed daily. The latter are often frothy (when starchy articles of food are taken), composed chiefly of fecal matter and undigested particles of food and mucus; and in severe forms blood and pus may be constantly present in the discharges. In many cases the stools are semifluid (pultaceous), and rarely they contain scybala; or the rather frequent liquid or semifluid discharges may alternate with constipation. The lesions are then apt to be situated in the lowest portion of the large intestine. The *character* of the discharges is much influenced by the sort of food taken; thus, when a mixed dietary is partaken of, they are thin, more frequent, and contain more undigested masses of food. *Gas-eous distention* of the intestines is often an annoying symptom.

The **physical signs** are negative, save only slight tenderness along the line of the colon.

Associated symptoms referable to other organs are not without value in the diagnosis. The gastric digestion is poor, the appetite generally impaired (though variable), and the *tongue* is clean, red, and glazed, presenting the appearance of raw beef. There are progressive *emaciation* and *asthenia*, which eventually reach an extreme degree. The skin-surface becomes dry, harsh, and cool, the facies grim, the pulse exceedingly feeble, the mental faculties greatly weakened in the advanced stage; and, as in the acute form so in the chronic, death is usually due to asthenia—with this difference, that in the latter the end is reached more slowly. Peritonitis in consequence of perforation is rare.

Differential Diagnosis.—The disease is to be discriminated from *chronic diarrhea*. In chronic dysentery there is the history of an antecedent acute attack, with the appearance from time to time of exacerbating periods when mucus, pus, and often blood are contained in the discharges. The latter are, at the same time, more frequent and apt to be accompanied by more or less abdominal pain and tenesmus, and the presence of these features would serve to eliminate chronic diarrhea. From *tuberculous ulceration* of the intestines it is distinguished by the absence of any history of tuberculosis, family or personal, and of tuberculous new growths in other portions of the body, particularly the lungs.

The **complications** are the same as in acute dysentery, if we except the greater liability, due to the great and protracted weakness of the patient, to certain serious intervening diseases (chronic nephritis, tuberculosis, pneumonia). Ulceration of the cornea has been noted.

The **duration** is long, the disease lasting for many months or even several years.

Treatment.—This should be directed mainly to the local condition, and should consist in methodic irrigation of the bowel with a view to promoting the healing of the ulcers. Formerly it was sought to accomplish the latter indication by the use of certain remedies internally, as silver nitrate, balsam of copaiba, bismuth subnitrate, etc., but the only preparation which I have found useful is the zinc oxid (gr. v-x—0.324—

0.648) three times daily. The latter preparation is decidedly palliative, sometimes even curative.

Intestinal irrigation is to be tried, and various disinfectants and astringent remedies should be alternated as advocated in the acute form. Among individual remedies the silver nitrate (gr. ss-ij—0.032-0.129—ad 3j—32.0) every second day is doubtless the best. On intervening days antiseptic remedies may be used in solution, such as mercuric chlorid (1:6000) or salicylic acid (1 to 2 per cent.); and of other useful agents I may mention tannic acid, alum, acetate of lead, and creolin.

Prior to the use of any of the above-mentioned enemata the bowels should be well flushed with a large injection of tepid water, so as to remove the fecal and other irritating materials. The same details are to be observed in carrying out this mode of treatment as in the acute forms of dysentery. Gallay¹ has related the curative effects of large enemata of a solution of crystallized silver nitrate in distilled water, a scruple to a quart (1.296 per liter), to which 20 or 30 drops of laudanum have been added. Amelioration follows the third or fourth washing, but a course of sixty is recommended to secure permanent relief. The lower part of the rectum should be examined with the speculum, and appropriate topical applications made if ulcers in this situation be discovered. It has been suggested that topical therapy can be facilitated in chronic cases by the production of an artificial anus, in the left iliac region, or an appendicostomy, but the value of the method is still doubtful.

The *dietetic* treatment in chronic dysentery is of the utmost importance, and light forms of proteids are to be selected, to the exclusion of vegetable substances. Milk is excellent when it can be taken. It is well to examine the stools, and if on microscopic examination curds or numerous fat-globules appear, the amount of milk should be reduced or skim-milk substituted. Egg-white, meat-broths or beef-juice, whey, and even light, nutritious solids may be allowed. The patient should wear flannels next the skin, and, while open-air exercise is useful, it should be moderate. During inclement weather the patient should remain in-doors. I have known change of climate, with proper regulation of the mode of living, to be productive of rather brilliant results. Tonics and alcoholic stimulants are sometimes required to assist the appetite, digestion, and systemic strength, and among the most efficacious tonic remedies are iron, strychnin, mineral acids, and arsenic.

CHOLERA (EPIDEMIC).

(*Asiatic Cholera; Cholera Algida, etc.*)

Definition.—Cholera is an acute, infectious, epidemic disease, due to the spirillum of Koch (*vibrio cholerae Asiaticæ*); and its characteristic symptoms are copious watery dejections, painful cramps, collapse, and suppression of the excretions. In some localities it is endemic.

Historic Note.—During the Middle Ages cholera made deplorable ravages, chiefly along the belts of the Ganges, and has probably been endemic in India for centuries. Only during the present century,

¹"Radical Cure for Chronic Dysentery of Recurrent Type," *British Med. Journal*, No. 1779, p. 276.

however, has the disease been widely known in Europe and America, and when it has appeared it has always been in the epidemic form. The march of epidemics has been from east to west, along the lines of commerce and travel by land or sea, sometimes spreading over the entire globe. Space forbids an account of the progress of the various cholera outbreaks in Europe and America. It may be stated that there have been no distinct epidemic visitations in America since 1873. In India, Mecca, Java, China, and in the Philippine Islands numerous cases appeared during the winter, spring, and summer of 1902.

Pathology.—The body is much emaciated, the features sharp and drawn, and the skin of the dependent parts presents a mottled appearance. A post-mortem rise of temperature often occurs. The tissues are dry, owing to the draining of the liquids of the body, and hence putrefaction is delayed. Rigor mortis comes on directly after death, is persistent, and the muscles often contract so as to cause the body to assume various uncommon positions.

The Visceral Lesions.—The chief of these are confined to the intestinal canal, and depend largely upon the period of the disease at which death occurs. In the early stage the serosa of the small bowel is congested, presenting a roseate hue. The muscularis is relaxed. The mucosa is the seat of catarrh, being deeply injected, swollen, at times edematous, and often coated in the early stage with more or less tough mucus. Shortly the coils of intestine are filled with an almost transparent or slightly turbid liquid ("rice-water"), and occasionally a small amount of clotted blood is seen. The solitary follicles and Peyer's patches are swollen, and, in rare instances, become ulcerated. Denudation of the epithelial lining—most probably a post-mortem change—is the rule, and ecchymotic spots are visible in the intestinal mucosa. If the patient has died late in the disease (stage of reaction), patches of false membrane may be found anywhere along the intestinal canal, although chiefly in the large bowel; and this secondary croupous-diphtheritic process may attack other mucous surfaces (bile-ducts, vagina).

The *stomach* shows changes similar to those found in the intestines. At first the mucosa is congested; then, as the result of transudation, it becomes filled with "rice-water" material. At last the organ is empty and collapsed. The *esophagus* also exhibits analogous lesions.

The *spleen* is small, as a rule, though if death occur late it may show some degree of enlargement with softening.

The *liver* presents marked passive hyperemia and cloudy swelling, with minute spots of beginning fatty change. Desquamation of the epithelium of the cystic mucosa may occur and block the bile-ducts.

The *kidneys* show important lesions, being enlarged from passive congestion, especially the cortex, and the capsule being somewhat adherent. They exhibit cloudy swelling and decided coagulation-necrosis. Desquamation of the epithelium in the uriniferous tubules is extensive. Microscopically, the histologic changes are those of acute nephritis in the cases in which death takes place in the advanced stage. The *bladder-changes* differ in no way from those of other mucous membranes. Its mucosa is congested, ecchymotic, and may show diphtheritic deposit. The ureters and the pelvis of the kidneys may present identical appearances.

The Circulatory System.—The pericardium is dry, the parietal layer being covered with an adhesive secretion, while the visceral layer is the

seat of ecchymosis. The heart is dry and anemic looking. The left ventricle is contracted, while the right is often distended with blood and soft clots. Outside of the heart the veins, including the cerebral sinuses, contain most of the blood. The blood is thick and its color dark, resembling "the juice of huckleberries"; its specific gravity, albumin, and corpuscles are all increased, while its coagulability is decreased.

Respiratory Organs.—The larynx, trachea, and bronchi are hyperemic, and at first covered with tenacious mucus; later they may present ecchymoses and diphtheritic processes.

When death occurs before the stage of reaction the lungs are bloodless, collapsed, and the mouth of the pulmonary artery may be distended. If life is prolonged until the third stage, the lungs may show congestion and edema or pulmonary infarction. The post-mortem may now also exhibit the lesions of broncho- or lobar pneumonia.

The brain and its membranes may be the seat of hyperemia, except when death takes place at a late period, and then the brain-substance may be more or less bloodless and edematous.

Etiology.—The causes are (a) *specific* and (b) *predisposing*.

(a) The specific cause is the spirillum of Koch, which is found in the intestinal canal of persons ill of cholera. Recent investigations into the bacteriology of the affection show that almost uniformly the cholera vibrio is associated with certain bacteria, most commonly the bacillus coli communis. True cholera is a *nitrite*-poisoning, the result of the growth of the specific spirillum. Koch's organism is not found in any other disease. Its form is that of a slightly curved rod, and its length about half that of the tubercle bacillus, but it is thicker and sometimes has the form of the letter S (Fig. 8). The cholera vibrio is motile, its motility being due to a single flagellum attached to one end. It has been grown successfully on media of various sorts (*e. g.* nutrient gelatine, forming colorless colonies and liquefying the gelatine) and equally successfully inoculated upon inferior animals.

FIG. 8.—Comma bacilli (from the mouth);
× 1000 (Günther).

The organism is found in a variety of positions—in the intestine, the dejecta (even quite early), and in great profusion in the pathognomonic "rice-water" stools. Kemp in his review has shown that the spirillum is often absent from the evacuations, and that in these cases the bacterium coli is usually present and sometimes streptococci. He believes, however, that the apparent absence is due to faulty technique. It may be seen in the stools and vomitus (rare) of well persons during epidemics, displaying virulent properties.

Outside the body they preserve their vitality in river or well water or upon the surface of moist linen for several weeks. C. Fränkel studied them in flowing water, and in other epidemic outbreaks they have been found in the water used for drinking purposes.

(b) **Predisposing Causes.**—(1) **Locality.**—Near to the sea-coast cholera is more common than in the inland districts or towns, and the frequency

of occurrence lessens with increasing altitude, this fact possibly being due to a gradual decrease in soil humidity and porosity.

(2) **Atmospheric Temperature.**—The spirillum of cholera can only flourish in a warm climate; hence the disease is *endemic* in certain tropical and subtropical climates; and hence also its *epidemic prevalence* is confined to temperate latitudes.

(3) **Seasons.**—For obvious reasons it is more common in the warm than in the cold months, most epidemics, both in Europe and America, having occurred toward the close of summer and in the early autumn. Winter frosts usually arrest an epidemic.

(4) **Age**, as a rule, has no decided effect. Old people, however, are very prone to the affection. **Sex** is without perceptible influence.

(5) **Debilitating Causes.**—Whenever the private conditions correspond to rigid scientific requirements during epidemic outbreaks cholera becomes less prevalent and also less virulent. On the other hand, the deplorable state of municipal sanitation, individual disregard of proper hygienic rules, nervous depression, intemperance, overcrowding, etc., all predispose markedly to the disease.

(6) Mere attacks of **intestinal disorder** due to improper diet, cold, etc., are potent to disseminate the disease.

Modes of Infection.—The spirilla leave the body with the stools, but the most frequent bearer of cholera-poison is the drinking-water. Naturally, the individual susceptibility varies greatly (many persons being even insusceptible), and yet the degree of contamination of the drinking-water and the virulence of epidemics are almost strictly proportionate. As an illustration, Vienna had enjoyed exemption from cholera for nineteen years—a fact attributed to the excellent quality of the drinking-water and to hygienic improvements. In the same city the mortality-rate in the more recent epidemics has been small (7 per 1000) for a like reason. On the other hand, in 1872 there occurred in a single commune (Hamburg), which had a polluted water-supply (the Elbe) and no filtration plant, 17,862 cases, with the enormous death-rate of 42.3 per cent. Koch holds that man, not noticeably diseased, is the real bearer and reproducer of the cholera vibrios.

The *choleraic poison* may be conveyed with the water used for washing, cooking, and other purposes to other fluids imbibed by man (beer, milk, tea), and also to food-stuffs taken by him (lettuce, cresses, and other raw vegetables, fruits, meats, bread, butter). The organisms live and maintain their virulence on these articles of food from four to seven days at least. The infection may reach the esophagus with the water used for washing the mouth or teeth, or that used for washing the utensils, dishes, food-receptacles, etc. Again, the hands, commonly those of laundresses and nurses, may become soiled in the careless handling of bed-linen or garments worn by cholera patients or the stools, and convey the poison to the mouth or lips, to be carried into the stomach along with the drink or food. Flies may transfer the infectious element to food-articles (Simmonds, MacKaig, and others).

Cholera is not contagious from mere contact with those ill of the disease. It is not acquired by inhalation (Shakespeare), and, since desiccation rapidly kills the organism, there is little probability that the latter is air-borne. Nor is there any clinical evidence to show that the poison may enter the system through the skin surface. Probably the germs are *swal-*

lowed, and the acid gastric juice may then destroy them if the size of the dose of the poison is not too large, or they may pass into the intestinal canal and there manifest pathogenic powers. After the spirillum reaches the intestine, whether or not an attack is the result depends both upon the size of the poisonous dose and upon the personal degree of immunity.

Opposed to the drinking-water theory of this disease is that of Pettenkofer, which contends that the spirilla found in the serous evacuations of cholera patients must enter an appropriate soil and there undergo further development before becoming pathogenic. While soils possessing a certain degree of moisture and perviousness and contaminated with organic matter favor the growth and multiplication of the specific organism, these telluric conditions are not essential, as is shown by the virulence of the stools when swallowed in ample quantity. Pettenkofer and Rubino¹ claim that the fully developed poison rises from the subsoil into the lower atmospheric strata as a miasm, especially at the time of the subsidence of the ground-water level in summer.

Immunity is not conferred by a previous attack of cholera. Pfeiffer and Marx have proved the existence in the blood-serum of human beings of bactericidal bodies (not a true antitoxin) that cause rapid destruction of the cholera bacilli. To these anti-bodies is ascribed the "Pfeiffer serum reaction," by means of which the vibrios are differentiated from other micro-organisms. Pfeiffer and Marx have also shown that the virus of cholera can be effectively preserved by a 0.5 per cent. solution of carbolic acid, and that it in no way impairs its immunizing properties.

Clinical History.—The incubation period varies from a few hours to five days (average two to three days). During this prodromal period the patient is either quite well or (during the latter portion) exhibits certain local symptoms. These are occasionally nausea, a feeling of distress in the abdomen, increased peristalsis which may be visible or palpable, slight pain and tenderness, and either a mild or a decided diarrhea. The discharges are feculent, colored, and semifluid, or, more rarely, quite fluid, and may be quite copious. These symptoms may all be present, though oftener a few, and rarely a single one, is noted; moreover, they are not distinctive unless seen during an epidemic and unless the patients have been exposed to the poison. *Prostration* may be marked and there may be slight muscular cramps. The so-called *premonitory diarrhea* may terminate in recovery at the end of from one to three days, or be followed by an attack of cholera. This has three stages.

(1) **Stage of Serous Diarrhea.**—The *dejecta* are generally painless, very frequent, odorless, copious, and fluid or watery, and usually present the characteristic "rice-water" appearance. Rarely they are distinctly colored with bile, and in severe cases with blood, and rarely also are they frothy. Suspended in them are numerous small, whitish, mucous flakes; their reaction is neutral or alkaline, and they contain a small percentage of solid constituents made up largely of albumin and sodium chlorid. The microscope brings to view epithelium, mucus, triple phosphates, and numberless micro-organisms, of which latter the only ones characteristic are the comma-spirilla of Koch. In *cholera sicca* these serous evacuations are absent. Death comes quickly, and post-mortem examinations show the intestine to be filled with "rice-water" material, which is probably retained because of speedy paralysis of the musculature.

¹ *Sajous's Annual*, 1899, vol. ii., p. 214.

Gastric symptoms appear early. Vomiting soon becomes frequent, and at first the vomitus may be bilious; later it is characteristically serous and excessive in amount. *Thirst* is almost intolerable, anorexia is complete, and the tongue often has a thick coating, which early becomes dry. Gastro-intestinal *pain* is not severe, but a feeling of pressure or burning in the abdomen is experienced, and occasionally there are griping pains with tenesmus. The *physical signs* are few. The belly is usually flat and flaccid, though it may be scaphoid and hard, and in some cases palpation detects fluctuation.

Painful cramps in the *muscles* form an early characteristic symptom. They affect the voluntary muscles of the legs, calves, and feet, more rarely the arms and hands also. Their duration is momentary, but they recur at intervals, and are due to the local action of the toxins.

Owing to the withdrawal of fluid from the lymphatics and blood-vessels the tissues become dry and shrivelled and the blood much thicker. This condition of the blood obviously increases the labor of the heart, which beats rapidly, and there may be at first a distressing palpitation; but soon the heart grows more and more feeble and venous stasis ensues. The *pulse* is at first rapid, soft, and small; it may then be lost at the wrist. The cardiac impulse and heart-sounds may at last disappear.

The *facies* and *general appearance* also indicate loss of fluid. The cutaneous surfaces of the face and extremities grow cool: there is rapid general emaciation, which may become most pronounced, and the skin is wrinkled. The complexion assumes a livid or blue-gray tint, while the lips become quite dark. The extremities are cyanotic (the finger-tips in particular), the orbits are deeply sunken, the cheeks hollow, the features intensely pinched, the voice husky and feeble, and there is utter prostration. The *surface-temperature* drops below the normal, even to 96° or 95° F. (35.5°–35° C.), while, *per contra*, the internal or rectal temperature rises to 102° F. (38.8° C.) or over. The *mind* may remain clear until the close, but oftener the patient is apathetic, and in grave cases this condition may deepen into stupor or even actual coma. The *reflexes* are greatly diminished. S. Rogers¹ found a variable degree of leukocytosis, and the large mononuclear cells were usually increased—an important diagnostic sign.

The *urine* becomes very scanty and is highly concentrated, the standing specimen depositing a heavy sediment. On analysis albumin and casts (chiefly granular) are found. In the serious forms the kidneys fail to eliminate the urea, and there is finally complete anuria.

(2) *Stage of Algidity or Collapse*.—The symptoms which characterize this grave condition are the same as those noted under the latter part of the first stage, only intensified. *Asthenia* is extreme; the *pulse* is missing and the heart beats faintly; the *voice* is lost; *respirations* are perceptibly shallow; lividity is intense; the surface ice-cold; and there is usually *stupor* or even *coma*. The excessive *serous discharges* have given place to mere dribblings from the now relaxed anus. During this stage, which may last a few or many hours, the faint glimmerings of the vital spark are often extinguished.

(3) *Stage of Reaction*.—This sets in promptly, and the case may pursue a favorable course, with return to accustomed health by the end of a week or ten days. The first urine passed is usually albuminous and contains tube-casts. *Relapses* into the stage of collapse may occur

¹ *Brit. Med. Jour.*, July 12, 1902.

and be repeated; in many instances, however, this stage is both protracted and dangerous. It is aptly termed *cholera typhoid*, since a genuine typhoid state develops. The *skin* may present so-called choleraic eruptions (macular, roseolar erythema). Recovery may now take place, or a great diversity of local secondary inflammation may supervene.

Acute nephritis may arise in this stage and lead either slowly or directly to uremic poisoning, as shown by the projection upon the scene of grave nervous phenomena—headache, vomiting, delirium or coma, and convulsions. A fatal result may be looked for.

Complications.—In this place are to be enumerated the conditions due to secondary infection, including (commonly) septic and pyemic processes. Diphtheritic inflammations affecting mucous surfaces, but especially the throat, colon, and the external genitals, are among the more common. Bronchitis, pneumonia, and pleurisy may arise, and erysipelas and parotitis are not rare. During *convalescence* digestive disorders may show themselves, and indiscretions in diet may precipitate a relapse.

Clinical Types.—(a) “**Premonitory Diarrhea.**”—This type has been outlined with sufficient fulness in the foregoing discussion.

(b) “**Cholérine,**” in which the symptoms are mild, resembling those of cholera nostras. Many of the symptoms characteristic of true cholera are also present, particularly the *cramps* and *prostration*, cold extremities, and scanty albuminous urine. The stools, however, are not typical of the disease, but are feculent in character, as in ordinary cholera morbus. The *duration* is from seven to ten days, subject to relapses.

(c) The more typical forms—both moderate and severe—have been described under the Clinical History (*supra*).

(d) **The Foudroyant or Asphyxic Form.**—This may kill instantly; more frequently the patient lives for a few hours, with or without vomiting and purging. *Cholera sicca* should be classed with this type. The virulence of the cholera-poison explains the intensity of the symptoms.

Differential Diagnosis.—This is difficult in the absence of an epidemic unless bacteriologic and microscopic tests be made, and yet these alone differentiate a sporadic case. The disease most commonly mistaken for cholera (especially cholérine) is *cholera morbus*, and the following points pertaining to the latter disease will eliminate it: 1. No connection with a previous case, but a frequent history of dietetic imprudence. 2. Absence of “rice-water” stools, which remain turbid with feces or covered with bile or blood. 3. Presence of colicky pains, but absence of painful tonic cramps of legs and feet. 4. Absence of cyanosis and collapse, as a rule, and of urinary suppression. 5. No cholera spirilla in the stools.

Arsenic-poisoning and other forms of *gastro-enteritis* must be discriminated by the history, the character of the stools, the absence of violent muscle-cramps and of the effects of great loss of fluid (cyanosis, shrunken body, profound collapse). Chemical tests are not to be neglected.

Prognosis.—This is dependent mainly on the type. Thus “cholérine” is very rarely fatal. It is impossible to state the average mortality, since it varies with each epidemic, but it has been found to range from 20 to 80 per cent. Many sufferers perish during the latter part of the first day or during the algid period; still more during the stage of reaction, the dangers of the latter period being as follows: asthenia,

cholera, nephritis with uremia, and the various complications (*vide supra*). The greater the difference between the surface temperature and that of the rectum, the more unfavorable the prognosis. The personal circumstances which render an attack grave are old age, alcoholism, previous ill-health, and debility. On the other hand, the death-rate may readily be lowered by prompt and judicious treatment.

Treatment.—**Prophylaxis.**—It has been owing in great measure to the efficient quarantine system of the United States that cholera has not gained a foothold on our shores since 1873.

Individual Prophylaxis.—In the first place, those nursing the sick can prevent the spread of cholera by prompt and thorough disinfection. The dejecta may be disinfected by pouring upon and mixing with them an equal part of a 5 per cent. solution of carbolic acid or an equal volume of a freshly prepared solution of chlorid of lime. The discharges thus treated must be covered and allowed to stand from fifteen minutes to half an hour, and then emptied into a pit in the earth containing quicklime, with which they should also be covered. It is of the utmost importance to guard against a pollution of the water-supply by these pits. Soiled clothing, linen, and the like should be promptly disinfected, and bedding had better be burned; none but the attendants should be permitted to enter the sick-room. The dishes used should be disinfected immediately after use or before leaving the sick-chamber. After handling the patient or anything that he has soiled the attendants should first disinfect and then carefully wash their hands. After vomiting and after an evacuation of the bowels the mouth and the parts around the anus should be wiped with a cloth wet with a solution (1:2000) of mercuric chlorid. The internal use of sulphuric acid is an important prophylactic. If convalescence supervene, the patient should be kept isolated for a week and the stools disinfected during that time.

Persons exposed should use boiled milk and water only. Certain forms of food must be avoided, especially salads and unripe fruits; also alcoholic stimulants. All uncooked food may be pernicious. Such persons should lead regular lives, avoiding fatigue, excesses, etc., and intestinal disturbance must be met speedily by the use of antiseptics, opiates, and astringents. In India, Haffkine¹ has used a protective virus with encouraging results. Thus, "of 1735 persons not inoculated in a certain section, 174 took the disease and 113 died, whereas of 500 inoculated but 21 were affected and 19 died." He has made, altogether, 70,000 injections in 40,000 patients without a single accident, and claims that the results have been entirely favorable. Klein concludes against Haffkine's anticholera inoculations, which, however, produce a temporary active immunity. Pfeiffer and Kolle's method, the injection of dead cholera vibrios, is to be preferred. Immunity as the result of vaccination is to be advised in countries where cholera is endemic and from time to time epidemic—*e. g.*, India. Kraus has obtained a specific toxin and antitoxin, but their practical value remains to be determined.

Treatment of the Attack.—(*a*) **Premonitory Diarrhea.**—In the instances which are not preceded by premonitory diarrhea opportunity to prevent the attacks does not present itself. To dispel the organisms from the intestinal canal, castor oil and especially a course of calomel have been used. In this stage a double indication is presented—"to restrain

¹ *Münch. med. Woch.*, Jan. 29, 1895.

the development of the bacilli in the intestine and to neutralize the cholera-poison." To meet this Cantani proposes tannic acid by irrigation (enteroclysis). He injects into the intestine $\frac{1}{2}$ to $2\frac{1}{2}$ quarts (liters) of water, or infusion of chamomile containing ziss to $3v$ (6.0 to 20.0) of tannic acid, gtt. xx to xxx (1.20) of laudanum, and $3v-xij$ (20.0–50.0) of gum arabic at a temperature of 80° F. Injections should be repeated four times a day, and in grave cases after each evacuation.¹ For the same purpose acetate of lead and opium, or large doses of bismuth, with or without Dover's powder, have been much employed.

(b) **Stage of Serous Diarrhea.**—The chief indication is to restore to the blood the watery elements withdrawn by the diarrhea. Not a moment is to be wasted. Opium, and preferably the salts of morphin, should be administered hypodermically, the dose not being small, but gr. $\frac{1}{4}$ to $\frac{1}{3}$ (0.0162–0.0216) to be repeated at intervals of about eight hours. To opium given *per oram* or in the usual way there is a serious objection—namely, its slowness of action. Cantani advocates the injection of an artificial serum (*hypodermoclysis*) containing 1 dram (4.0) of sodium

FIG. 9.—1, fountain syringe; 2, cock; 3, attachment for cannula; 4, needle; 5, cannula; 6, soft-rubber rectal tube, with two lateral openings, one a half inch from the end (not visible), the other two inches from the end. The latter is to be introduced by a combined rotatory and pushing motion to the depth of ten inches in enteroclysis, and the fluid then allowed to enter the colon slowly.

chlorid and gr. xlvj (3.0) of sodium carbonate per quart (liter) of sterilized water warmed up to 104° F. (40° C.) into the subcutaneous connective tissue. This solution may be introduced through the cannula of an ordinary aspirator, the fluid flowing by gentle pressure. Shakespeare recommends for hypodermoclysis a fountain syringe with a long flexible tube furnished with a cock; with another shorter tube, one end attached to the cock, the other having a needle-pointed cannula, a little longer, stronger, and with a somewhat wider caliber than the ordinary hypodermic needle (Fig. 9). The tube and cannula are first perfectly filled with a fluid, and then the cannula is inserted well in between the skin

¹ *Annual of the Universal Medical Sciences*, 1893.

and deep fascia of the flanks, buttocks, or interscapular region. The fluid should be made to flow slowly, allowing fifteen to twenty minutes for the introduction of 1 quart. This is preferred to intravenous injection, in which the liquid is diffused slowly.

The *vomiting* is to be relieved by bits of ice, small amounts of brandy and water at brief intervals, cocain, or by *lavage*. In this stage remedies by the mouth should be avoided, since they aggravate the gastric disturbance. Thébaud has treated 8 cases of cholera in Indo-China with a 3:1000 solution of sodium bicarbonate, to drink freely, up to 3 quarts a day. Heat should be applied externally with a view to assisting the peripheral circulation, and thus obviating collapse. Warm baths have been recommended for this purpose. Stimulants must be used to fulfil the same indications. They are of superior value even to the above-mentioned measures, and are to be given hypodermically, and either brandy, ammonia, or strychnin may be employed in large doses.

(c) **Stage of Algidity.**—If this develop, the case is desperate. In this stage the following measures and procedures, which have been detailed in the treatment of the preceding stage, are to be persevered with enteroclysis and hypodermoclysis, hypodermic stimulation, and the external application of heat. Additionally, intravenous injections of fluids have been strongly urged by informed observers. For this purpose the following standard of saline fluid may be chosen: sodium bicarbonate 1 part, sodium chlorid 6 parts, boiled water 1000 parts. The temperature of the fluid when injected varies according to circumstances from $100\frac{3}{4}^{\circ}$ to 104° F. (38° to 40° C.), more frequently the latter (Shakespeare). The quantity demanded may be 1 or 2 quarts (liters), and the injection may need to be repeated in from one to three or four hours. Morphin (in small doses) and strychnin, hypodermatically, should also be used.

(d) **Stage of Reaction.**—During this stage the tannic acid may be replaced by a solution of salt in water (10 or 15 per cent.) for enteroclysis (Cantani), and it may be well to continue hypodermoclysis in some instances. Further than this, the treatment is essentially symptomatic. Food of the blandest sort and in small quantities must be allowed at frequent intervals if we would avoid enteritis and other unfavorable complications. Tonic remedies should be given cautiously, and rest and careful nursing insisted upon. Complications must be met in accordance with general principles.

Reference should be made here to the antitoxin and the vaccine that are being used by the Japanese in treating this disease. Schurupow's serum has given good results on therapeutic trial.

YELLOW FEVER.

(*Febris flava*; *Gelfieber*, Ger.)

Definition.—Yellow fever is an acute, highly infectious (but non-contagious) epidemic and epidemic disease. It is characterized by a sharp period of invasion, followed by a period of remission, and the latter in turn by a relapse and certain symptoms peculiar to the affection (black vomit, jaundice, suppression of urine).

Historic Note.—Yellow fever is endemic only within certain geographic limits, where it also prevails epidemically when the conditions are favorable. According to general belief, it first appeared in 1647 in the

Barbadoes (West Indies). Subsequently, it was conveyed along the channels of commerce until it became widely disseminated, and chiefly in sea-port towns. In 1699 an English vessel carrying slaves transported the disease to Mexico from the Atlantic coast of Africa. Guit  ras classified the areas of infection thus: (1) The *focal zone*, in which the disease is never absent, including Havana, Vera Cruz, Rio, and other Spanish-American ports. (2) *Perifocal zones*, or regions of periodic epidemics, including the ports of the tropical Atlantic coast in America and Africa. (3) The *zone of accidental epidemics*, between the parallels of 45   N. and 35   S. latitude. Yellow fever was brought to the United States (Boston) in 1693, and since then has invaded in epidemic form numerous sea-coast cities, being carried thence to a number of inland towns. For example, in 1853 the disease prevailed throughout the Southern States, and since then six epidemic outbreaks (1867, 1873, 1878, 1897, 1898, 1899), though of lesser severity, raged in the same section. The disease has been conveyed to seaports in Great Britain and France, but has never been carried inland in those countries. The belief that the disease never originates outside of certain territorial limits was advanced for the first time by the College of Physicians of Philadelphia (1797).

Pathology.—The *skin* is jaundiced, and often ecchymotic spots are observed, but the internal viscera show no characteristic lesions in cases of average intensity. In severe forms congestion, hemorrhage, degeneration, and necrosis are the changes noted.

After death the *liver* is anemic, as a rule, but in the early stages of the disease it is markedly hyperemic. Its color varies, ranging from pale yellow to an orange hue, and punctiform extravasations cause mottling of the surface. Its size varies little from the normal. Parenchymatous degeneration of the hepatic tissue is common, though in places it may be entirely normal. The liver cells are swollen, containing fat and granular matter, with indistinctness or absence of nuclei.

The *gastro-intestinal mucosa* is the seat of acute catarrh (in severe types) and numerous minute hemorrhages, similar spots of extravasation being found on the various serous membranes of the body (meninges, pericardium, pleura, etc.). Hemorrhagic infarctions may be found in the various internal viscera. The black-vomit material is found in the stomach, and less frequently also in the smaller intestines.

The *spleen* is dark and friable, but is not enlarged. The *kidneys* show the lesions of diffuse nephritis, the microscope revealing cloudy swelling of the epithelium of the tubules, with fatty degeneration and tube-casts. The *heart-muscle* looks pale, and may be the seat of granular and fatty degeneration. The *brain* and its *meninges* are hyperemic, and degenerative changes occur in the sympathetic ganglia (Schmidt).

The *blood* is dark, and many of the red corpuscles, having disorganized, set free hemoglobin, as in malaria. Fatty degeneration of the walls of the small blood-vessels and the capillaries have been noted, and these, by allowing filtration of blood-serum, produce concentration of the blood. General glandular enlargement is often found.

Etiology.—**Bacteriology.**—At present writing, nothing is known of the micro-organism that causes this disease. H. Seidelin, however, has observed in the red blood-cells certain ring-like and ameboid forms which he believes have an etiologic relation to the disease. The infective character of the complaint is shown by the fact that it can be produced by

the inoculation of a susceptible person with the blood of a patient suffering from the disease.

Mode of Transmission.—The work of the Yellow Fever Commission of the U. S. Army (Drs. Reed, Carroll, Lazear, Agramonte) having thoroughly overthrown the claims of Sanarelli, that the bacillus *icteroides* is the specific cause of yellow fever, his bacillus is now regarded as a secondary invader. In 1881 C. J. Finley¹ pointed out that the disease is transmitted through the agency of the mosquito. It, however, remained for the commission mentioned above to furnish incontestable experimental proof that yellow fever is a mosquito-borne affection. They have shown that the *stegomyia fasciata* is probably the only carrier of the infecting agent. Twelve days after biting a yellow-fever subject the bite of the mosquito will infect a non-immune person. The insect is capable of infecting man for a period of several weeks. There is some evidence that the mosquito, once infective, is capable of transmitting the parasite for the balance of its life. The mosquitoes, however, are not infected by biting the dead bodies of yellow-fever patients, it being only during the first few days of the disease that the patient's blood is infective for the mosquito, and only the female mosquito bites. The clothing, vomitus, urine, and feces are non-infectious.

The *stegomyia fasciata* has been found as far north as Charlestown, S. C., and southward to the Rio de la Plata, and is extremely prevalent in Cuba. The larvæ only develop in comparatively clean water, and seldom breed far outside a city's limits. Yellow fever is thus a domiciliary infection. They bite principally late in the afternoon, and are not capable of long flights unless assisted by winds. The *stegomyia* only travels when it gets into a car, box, or drawer instead of a house; it "will not voluntarily leave a house, much less cross a street" (White).

Among *predisposing causes*, *season* heads the list. The disease prevails chiefly in summer, being completely arrested by one, or at most two, severe frosts. *Age* and *race* have some degree of influence, children being more liable than adults, males than females, and whites than blacks. The poison is not transferred by *fomites*. The march of an epidemic may be interrupted or even completely arrested by apparently trivial agencies—*e. g.*, watercourses, rows or clumps of shrubbery. One attack usually bestows permanent *immunity*, and natives of an infected district are far less liable to the disease than newcomers. Two attacks, however, have been reported (Boseman, Libby).

Clinical History.—**Incubation Stage.**—This varies, ranging from two to five or more days. During the incubation symptoms may appear, such as languor, headache, anorexia, but are not common.

Invasion Stage.—The *onset* is abrupt, an initial *chill* usually occurring, but it is very seldom severe or prolonged, a reactionary fever following promptly and the *temperature* rising to 103°, 104°, or even 105° F. (40.5° C.). The temperature is apt to be highest at the beginning, and then declines by lysis with slight evening exacerbations and morning remissions. Hyperpyrexia occasionally occurs on the first day of the illness. The chill and fever are accompanied by headache and pains in the loins and legs, often of great severity, and a little later, restlessness,

¹ *Annales de la Biol. Academie*, vol. xviii., pp. 147-161.

mental confusion, and a delirium that is sometimes violent in character may develop. In the majority of instances, however, the mind remains clear. The *pulse* is accelerated, but not in proportion to the height of the temperature; it is full and strong at the start, and is observed to fall while the temperature remains the same or even rises. The *face* is flushed, with slight icteroid addition. The early manifestation of jaundice is the most characteristic feature of the facies (Guiteras). The eyes are suffused and intolerant of light. The *gums* may be swollen and spongy; later on a red line is seen at their margins and they readily ooze blood. The *tongue* may or may not be coated, and nausea and vomiting may occur, the latter being one of the most characteristic symptoms of the disease. Associated with these symptoms there are epigastric oppression and burning sensations, with decided tenderness. The *vomit* may be blood-streaked or contain chocolate-colored particles, and occasionally unaltered blood is vomited. Constipation is usually present, the stools showing a deficiency of bile. The *urine* is diminished in amount, dark-colored, and often contains a slight amount of albumin: this *early transient albuminuria* is a very characteristic symptom. The *initial stage* may last from six or eight hours to two or three days, or even longer, and is longer in the milder forms. With the termination of this stage there is a marked remission of the fever and other symptoms, the pulse becoming remarkably slow.

Stage of Remission.—From this moment convalescence may begin and proceed to full recovery without interruption, the happy event being often marked by critical discharges. In most instances, however, the patient presents certain symptoms and signs of ill-health during the stage of calm (more or less prostration, epigastric distress with tenderness, mental dulness or even stupor, and a yellowish tint of skin and urine), which lasts from a few to twenty-four hours, when another serious stage supervenes.

Stage of Secondary Fever or Collapse.—The patient becomes extremely weak, presenting the signs of profound *collapse*. The surface of the body is cool (extremities often positively cold), the skin in nearly all instances assuming a yellow or bronzed tinge. It is rarely absent during life, but always present after death. The *pulse* is rapid and compressible, and soon vomiting becomes distressing. *Hemorrhage* into the stomach occurs, the blood being acted upon by the gastric secretions, and producing the material which is expelled as the characteristic "*black vomit*." Occasionally unaltered blood may be vomited; the stools also may be tarry. In the worst cases hemorrhages from other mucous surfaces are common (epistaxis, hematuria, metrorrhagia, etc.), and cutaneous hemorrhages also now occur. In this stage the *tongue* becomes dry, brown, or even black; less frequently it is smooth, red, and fissured.

In most cases the *urine* is deficient, containing albumin and casts (with careful centrifugation), and in rare instances there is complete anuria. The latter may precede the development of grave *nervous symptoms*, as convulsions, or even coma, which may be uremic.

In some instances the *temperature* rises during this period (secondary fever), and in favorable cases terminates by lysis, or it may assume the typhoid form and result fatally, and a decided slowing of the pulse may occur, as low as twenty-four beats even. In all cases that pursue a favorable course convalescence is slow and gradual, and it may be interrupted by certain complications (*e. g.*, abscesses). The *duration* of the

entire attack (composed of three stages) is variable, though as a rule it covers about one week.

Clinical Varieties.—Many different varieties have been described, each characterized by one or more prominent features, but none seem more justifiable than Finlay's¹ classification, in which he distinguishes three forms: (1) the *acclimation fever*, or *non-albuminuric yellow fever*; (2) the *plain albuminuric yellow fever*; (3) the *melano-albuminuric yellow fever*, characterized by the presence of blood or "black vomit" in the stomach or intestines. Relapses occur, but are rare.

Diagnosis.—The symptoms that justify a diagnosis in the initial stage, provided an epidemic be prevailing, are the sudden onset, severe nephralgia, cephalalgia, peculiar facies and pulse (a fall in the pulse-rate while the fever remains high or rising—Faget's sign), nausea, and vomiting of bile. In the early stage intense capillary congestion of the surface of the body is diagnostic and indicative of a severe type. In the third stage the co-existence of jaundice, the black vomit, and suppression of urine, with evidences of collapse, make the diagnosis easy. The mild or rudimentary form offers the greatest difficulty, since the clinical picture comprises only slight fever which, at the end of a day, is followed by speedy convalescence.

Serum diagnosis.—Woodson and P. E. and J. J. Archinard have applied the Widal reaction (agglutination-test) in 100 cases, and claim that the serum-diagnosis of yellow fever is practicable and may be used on the second day. A dilution of 1 : 40 is advised.

Differential Diagnosis.—*Pernicious malarial fever* (estivo-autumnal) has not the early, deep jaundice, the slow pulse, the peculiar temperature-curve, the intense capillary congestion of the surface of the body, the black vomit, the early albuminuria, and the clear mind—all symptoms that mark yellow fever. On the other hand the crescentic or small ring-shaped forms of the plasmodium are pathognomonic of pernicious malarial fever, as is the effect of quinin upon the disease. Kemp has made a microscopic, spectroscopic, and chemical study of the black vomit of yellow and malarial fevers, and found that the pigment was derived from the blood, which had been acted upon by the gastric juices. The vomitus in malarial fever, however, contains in addition considerable quantities of bile-pigment and bile-salts, which are wanting in that of yellow fever. Further, in the latter, the vomited matter is much more highly acid. The diagnostic features of *dengue*, which has been confounded with *febris flava*, have been contrasted with those of the latter disease on p. 140.

Prognosis.—Different epidemics show widely different death-rates, and the most potent factor is the particular type of the disease in individual epidemics. Some outbreaks have been characterized by the lighter forms, and in such the death-rate has been low (1 per cent.). In other epidemics the type has been so virulent (with high temperature) as to make the mortality list high—even to 100 per cent. In general, mild epidemics give a mortality of 5 to 10 per cent., and severe ones of 30 to 50 per cent. The death-rate is lower in private than hospital practice.

Among the gravest symptoms are *intense capillary congestion*, coming on during the first stage, *suppression of urine*, *intense jaundice*, and *uremic toxemia*. The black vomit is not as fatal a sign as the symptoms previously mentioned.

It has been noted that a larger number of men, proportionately, than

¹ *Edinburgh Medical Journal*, Edinburgh.

women and children succumb to the disease, and that it is less fatal among negroes than among whites.

Treatment.—The measures that are employed in yellow fever may be considered under three main heads: (1) Prophylaxis; (2) general management; and (3) medicinal measures.

(1) **Prophylaxis.**—Reed claims that the present quarantine laws against yellow fever are needless and the detention system absurd. The effective way to prevent carrying of the fever poison is the destruction of the *Stegomyia fasciata*—on vessels at sea as well as in infected houses and districts on land. Well persons must be protected against the bites of the *Stegomyia* by careful screening. It is a twilight mosquito, resting in the middle of the day, hence non-immunes may visit infected localities between 9 A. M. and 3 P. M. with impunity. It is unnecessary to disinfect articles of clothing, bedding, or merchandise supposedly contaminated by contact with those ill of the disease. W. C. Gorgas¹ has shown that in Havana, since attention has been directed entirely to the mosquito, the minimum annual death-rate from yellow fever has been reached. The patient must be isolated and carefully screened.

“When a non-immune is going to be exposed to yellow fever it is better to be inoculated, so that he can be put to bed and treated from the beginning, than to take it accidentally” (Gorgas). To immunize a patient a single mosquito should be employed for each inoculation.

(2) **General Management.**—The sufferer from yellow fever must be put to bed at once, and an abundance of fresh air (without exposure to strong drafts) must be supplied. The medicaments and the nourishment are to be administered through a tube or spout-cup, so as to obviate raising the patient's head. Body- and bed-linen should be kept scrupulously clean, and the patient must not be allowed to leave his bed on any account. The diet should be of the lightest sort and entirely liquid, beginning with peptonized milk, koumiss, or light broths.

(3) **Medicinal Measures.**—At the outset it is well to gently stimulate the various excretory organs, and mild laxative diaphoretics and diuretics answer this purpose. Hydrotherapy may be employed to maintain the nervous tonicity and reduce the temperature, but when the spontaneous fall of temperature sets in it must be discontinued. The neuralgic pains, which attack principally the head, loins, and nerve-trunk, are to be relieved by morphin given hypodermically; and for the same symptom Bemiss highly recommends quinin by the rectum (gr. xx—1.296). Intestinal antiseptics may also be used throughout the attack.

During the stage of *remission* the powers of the system are to be fully maintained by a suitable dietary and by tonics and stimulants if required.

In the last stage, supportive measures must not be forgotten. *Rectal nutrient enemata* should be employed if marked gastric irritability prohibits feeding by the mouth. *Stimulants* are demanded, and these should also be administered per rectum if not retained by the stomach, or they may in some measure be administered hypodermically. The stomach is, as a rule, tolerant of iced champagne.

If irritability of the stomach be present, ice and hydrocyanic acid may be tried. Sodium bicarbonate (gr. x to xx—0.648 to 1.296) in Vichy, Apollinaris, or Seltzer water is a most useful remedy, and Stern-

¹ *Phila. Med. Jour.*, Jan. 4, 1902.

berg has used it in combination with mercuric chlorid with success in the following formula :

| | |
|----------------------|------------------|
| R. Sodii bicarb., | ʒiv (16.0); |
| Hydrarg. bichlorid., | gr. ss. (0.032); |
| Aquæ puræ, | Oj (480).—M. |

Sig. For a severe case two teaspoonfuls every hour, day and night; for a mild case, every hour by day and every two hours by night; administer always ice-cold.

Perhaps the chief indication for the use of sodium bicarbonate is the extreme acidity of the various secretions, especially the gastric and renal. Sternberg contends that by fulfilling this indication we prevent in great measure the occurrence of acute nephritis and suppression of the urine. Hemorrhages and other symptoms must be treated by the usual means. During convalescence tonics are to be administered, and the customary diet can gradually be resumed.

Serum-therapeutics.—Prof. Sanarelli records favorable results from the use of his antitoxic serum. Morcour¹ points out that we need to try the serum only in grave cases, since mild cases recover with simpler methods and careful nursing. Wasdin, however, used Sanarelli's serum in 3 cases and noted no advantage over other treatment. Matienzo,² after a series of experiments on guinea-pigs and human beings with American serum, concludes: Intravenous and subcutaneous injections produce general reaction; no effect is produced upon the disease. The reaction obtained in convalescence proves that the antitoxin does not produce the cure.

CEREBRO-SPINAL MENINGITIS.

(*Spotted Fever; Cerebro-spinal Fever.*)

Definition.—An infectious disease, caused by the diplococcus intracellularis meningitidis (Weichselbaum). It is characterized anatomically by inflammation of the meninges of the brain and spinal cord, and clinically by an irregular course, a moderate febrile movement with somewhat characteristic and profound nervous symptoms (excruciating headache, pain in the back and upper part of the spine, contraction of the muscles of the nucha, hyperesthesia, delirium, and oftentimes coma). The disease may occur sporadically or in epidemics, or may even assume pandemic proportions.

Historic Note.—Cerebro-spinal meningitis was first recognized and described as late as the beginning of the last century (1805) by Vieusseux of Geneva. During the next decade numerous limited epidemics were observed both in Europe and the United States, and subsequently recurring epidemic and pandemic visitations were noted, though

¹ *Proceedings Third Pan-American Medical Congress*, Feb. 4, 1901.

² *Med. News*, Jan. 13, 1900.

at longer and variable intervals of time. In nearly all the large cities in this country it has become endemic, and in Philadelphia since 1863.

Pathology.—The cases that prove speedily fatal do not present gross characteristic changes, but by the aid of the microscope leukocytes are discovered immediately around the cerebral vessels, and round cells in the cortex of the brain. In some cases the characteristic evidences of encephalitis are already noticeable. On the other hand, the cases in which death occurs after the disease has been fully developed show the lesions of suppurative inflammation of the meninges of the brain. The arteries, veins, and sinuses are much engorged; the ventricles are distended with liquid, but the pia mater is principally affected, its vessels being greatly enlarged, and a more or less copious sero-fibrinous or sero-purulent exudate occurring into the meshes of its network. The longer the duration of the case the more purulent is the exudation. The ventricles of the brain are filled with a similar exudation, and red blood-globules may be present at an advanced stage. The color of the exudate is at first almost clear (being composed of serum); it then changes to a milky turbidity, to a pale yellow, and, lastly, takes on a greenish-yellow color ("leek-green"). The subarachnoid space may be occupied by a uniform layer composed of fibrin and pus.

The brain-matter is congested, and sometimes softened in spots, and on section the gray matter may present punctate extravasations. When resolution occurs recovery may be complete, but frequently the pia mater remains thickened. The exudation may follow the auditory and optic nerves along their lymph-sheaths, and pus has been found in the internal ear as well as in the chambers of the eye.

The membranes of the spinal cord manifest lesions identical with those of the brain. They are vascular engorgements, followed by sero-fibrinous, and later still by sero-purulent, exudation beneath the arachnoid. The changes are more marked on the posterior than the anterior surface of the cord, and the exudate increases in amount in passing from above downward, in severe cases sometimes assuming the form of a sheath which completely surrounds the cord throughout its entire length. The pia mater is congested, and may be thickened, shaggy, and in places adherent to the cord, of which the gray matter may be the seat of serous infiltration, and rarely of softening. Barker describes certain changes that occur in the nerve-cells and the ventral horns of the nucleus dorsalis (Clarkii) of the spinal cord in epidemic cerebro-spinal meningitis.

The lungs may exhibit the changes peculiar to bronchitis or pneumonia. In the heart endocarditis may be noted, though rarely, and both the pleura and the pericardium may show inflammatory lesions and contain a serous or sero-purulent exudation. Hemorrhages into the serous membranes and into the skin may take place. The spleen may be enlarged, the increase in size and the degree of fever being proportional, and the liver is hyperemic. The kidneys are congested, and bacterial forms have been found associated in the latter with the lesions of acute nephritis and hemorrhage—conditions of which they were probably the cause.

Etiology.—**Bacteriology.**—The diplococcus meningitidis is the specific cause of epidemic cerebro-spinal meningitis. The special organism

can be isolated from the spinal fluid, the meninges of the brain and cord, the blood, the joint-lesions, and the nasal mucus.

The meningococcus, like the gonococcus, occupies a position within the polynuclear leukocytes, but never appears within the nucleus (Park), and like the latter is biscuit-shaped. The bacterium takes the usual stains. It develops upon agar-agar and upon Loeffler's blood-serum, manifesting characteristics of growth that simulate those of the pneumococcus. Councilman, Carl Fränkel, Boston, and others, by refined methods, have, however, been able to differentiate these organisms. Welch suggests that the meningococcus and the pneumococcus are possibly varieties of the same bacterium, while Netter regards the meningococcus as a degenerate form of the pneumococcus. Among the associated microbes are the pneumococcus, streptococcus pyogenes, staphylococcus aureus, bacillus coli communis, and the tubercle bacillus, and any one of the latter is capable of causing sporadic cerebro-spinal meningitis.

Predisposing Causes.—(1) **Age.**—Most cases occur in children and young adults, though no age enjoys perfect immunity. Of 94 cases occurring in children up to 15 years of age, 56 were under five years (Claytor).

(2) **Climate.**—The disease is unknown in tropical climates, but has occurred in all parts of the temperate zone, and is most prevalent in the more northerly portions of the latter.

(3) **Season** is not an important factor, though the disease prevails largely in winter and spring.

(4) **Unhygienic Influences.**—The disease often appears in ill-ventilated and overcrowded habitations—among the poorer classes, among soldiers crowded together in barracks, and among prisoners. Prolonged marching, and excessive physical or mental exertion, may heighten susceptibility. In certain epidemics the disease has raged exclusively in villages.

Modes of Conveyance.—Precisely how the contagion is transferred from an infected person to a healthy one is not known, but the disease is probably contagious. Hare¹ has recorded two cases in which the infection seemed to be transferred directly from the first to the second. The poison may be conveyed by *fomites* in cases that furnish intensely virulent poison. As to the manner in which the virus gains entrance to the system, our knowledge is imperfect, although Hunt² states that cerebro-spinal meningitis seems to be an inhalation disease. It is certain that this germ may enter the meninges (*a*) by blood metastasis; (*b*) by direct extension of an adjacent inflammatory process (*e. g.*, mastoiditis). Elser and Hontoon³ believe that the disease may be spread by meningococcus carriers.

Clinical History.—The period of incubation is brief, though unknown. The *prodromal symptoms* are variable in different epidemics. Invasion may be sudden, a patient in vigorous health often being stricken down as though by a blow. In some rapidly fatal cases there is a short prodromal period, during which the patient complains of lassitude, headache, rachialgia, muscle- and joint-pains, and sometimes nausea and vomiting. In ordinary forms the prodromes may last from a few hours to a week or more, and the patient's complaint may be limited to cervical and occipital pains lasting a day or two; then, without any initial chill,

¹ *New York Med. Jour.*, Feb. 10, 1906.

² *Boston Med. and Surg. Jour.*, Nov. 1, 1906.

³ *Journal of Medical Research*, 1909, p. 397.

the *invasion-period* supervenes. In milder and sporadic cases the symptoms consist chiefly of languor and debility, headache, pain in the back and limbs, vertigo, vomiting, and sometimes diarrhea.

Most cases begin *abruptly*, between noon and midnight. The most distinctive and violent features are chill (often severe), *fever* of a moderate grade, a full and somewhat *accelerated pulse*, *raging headache*, and *vomiting*. In children the ushering-in symptom may be a *convulsion*. These phenomena are followed by pain in the back and cervical portion of the spine—an early and characteristic symptom. Attempts at flexion or rotation of the head increase the pain in the neck and movements of the body augment the spinal pains. Later, the muscles in the cervical region contract, at the same time becoming rigid, and produce the condition of opisthotonos. The patient may be unable to swallow.

The *temperature* is but moderately elevated. In a certain percentage of the cases it rapidly rises to 104° or 105° F. (40.5° C.), but soon falls to 102° or 103° F. (38.8° or 39.4° C.), at which level it is maintained with irregular undulations until defervescence, which takes place by lysis. In fatal cases death is preceded by a sudden great elevation of temperature to 108° and even 110° F. (43.3° C.). In the very young the thermometric range is lower than in adults.

The *pulse* is but slightly accelerated, if at all, in the early stages of the disease. Later, in twenty-four to thirty-six hours, it may in severe cases leap to 120 or even 140, its chief characteristic being the variability in its rate. In the early stage it is of good volume and tension; later, it may be soft and compressible, and in serious cases it becomes small and feeble. Polynuclear leukocytosis, moderate or severe, is constant.

The *respirations*, as a rule, increase in frequency and are sometimes quite irregular; but marked dyspnea, with slowing of the respirations, may be observed during the advanced stage, being due to pressure exerted by the exudation upon the respiratory center. Cheyne-Stokes breathing and sighing respirations may be present.

Nervous Symptoms.—The *headache* is racking and often persistent, though it is subject to remissions; it is intensified by light and sounds. There is vertigo in nearly all instances. The *pain* referred to the spine may be general or limited to either the lumbar or cervical region (rarely the dorsal), and the general myalgic pains are often intense, especially in the extremities and the abdominal region. With the cephalalgia and abdominal pain may be associated *vomiting*. *Hyperesthesia* is a prominent symptom, the gentlest touch being extremely painful; and *anesthesia* may follow. Any voluntary muscular movements, however, excite pain. In some cases *delirium* appears early, and in others rather late, while in the worst types death often occurs before delirium develops. On the other hand, in a small percentage of cases, this symptom is absent throughout the entire course, and always its character and intensity exhibit a remarkable variety. It may be mild or it may take the form merely of incoherent answers to questions. Active delirium, however, is common and is accompanied by hallucinations, during which the patient shouts loudly, and, unless restrained, gets out of bed. This form of delirium occurs in paroxysms that are most apt to appear at night, and in the female it is sometimes hilarious or hysteric. An erotic tendency, with priapism or seminal emissions, has been observed in males. The “maudlin”

delirium of the drunkard is sometimes seen, but sooner or later somnolence appears and may deepen quickly into coma, perhaps temporary, though more often it continues until recovery or death. Vomiting is common, usually late in the disease; it is doubtless of cerebral origin.

Symptoms of motor irritation are common, twitching of single muscles or groups often being seen, and occasionally muscular tremors. Muscular contraction is an almost constant feature. After a few days a tonic spasm of the muscles of the extremities sets in, bending the arms upon the chest, the forearm upon the arm, and the thumb upon the palm; the thigh is also flexed on the abdomen and the leg on the thigh. The opisthotonos may be followed by trismus, which can be considered a mortal symptom. Convulsions do not occur in adults, but are common in children; occasionally there is paralysis (facial hemiplegia).

Organs of Special Sense.—*Photophobia* is a prominent symptom, and the condition of the *pupils* is very variable. They may be dilated or contracted (more frequently the former) or remain normal; and in the majority of cases they are unequal in size and react poorly to light.

Strabismus is frequent, usually temporary, though it may recur during the attack. Rarely it is permanent. *Conjunctivitis* of moderate intensity and *keratitis* may occur, the former being common. Burville-Holmes¹ invites attention to anesthesia of the cornea and conjunctiva, which occurs in about one-half of the cases. *Ptosis* is almost always present. Intense purulent *irido-choroiditis* sometimes occurs; either temporary or permanent *blindness* and, rarely, *nystagmus* are noted. Among optical sequelæ are cataract and atrophy of the eyeball.

Deafness is common, there being an early intolerance of sound and a marked tinnitus aurium. Late suppurative inflammation of the middle ear, followed by rupture of the tympanum and *otorrhea*, may occur. The internal ear may be similarly involved, with uncertain *gait*.

Cutaneous symptoms appear, some of which possess considerable diagnostic worth. *Pallor* and *lividity* of the skin and visible mucous membranes often characterize the period of invasion, and shortly after the onset *herpes facialis* appears in more than half the cases. This symptom is significant for diagnosis. The separate lesions are extensive, and often coalescence of two or more is witnessed. Herpes facialis belongs in a peculiar sense to cerebrospinal meningitis; herpes labialis to malaria, and less frequently to pneumonia and meningitis. A *petechial eruption* is common, in the early epidemics, and more frequently in America than in Europe. To this symptom the disease owes the name, long since given to it, of "spotted fever." It may, however, be absent, and when present it is sometimes limited to a small superficial area, though more frequently it is diffuse. At first the eruption may be bright red (erythematous), later becoming darker, or it may be distinctly petechial from the start; purpuric spots of considerable size and sometimes large ecchymoses may appear, but these are most common in the more malignant types. Other forms of eruption are also seen (sudamina, urticaria, ecthyma, erythema, erysipelas, etc.), but are devoid of diagnostic value. *Gangrene* of the skin is occasionally noticed, and in some cases bed-sores are liable to arise; but there is no fixed time for the skin-lesions of cerebro-spinal fever to appear, and their duration is exceedingly variable.

¹ Jour. Amer. Med. Assoc., 1908, 1, 280.

Of **gastro-intestinal symptoms** *vomiting* is the most common. It usually lasts only for a brief period at the onset, though it may recur later at longer or shorter intervals, and is of nervous origin. The *appetite* may be good, but in many cases it is soon lost, the *tongue*, in a large proportion of the instances, being only slightly coated. In cases assuming the adynamic or *typhoid type* the tongue is apt to become dry and of a brown color, with the formation of sordes. Under these circumstances the abdomen is tympanitic and the bowels relaxed, and diarrhea may be urgent, resisting all efforts aimed at its relief. Retraction of the belly is common, and *constipation* instead of diarrhea is the general rule; the spleen may often be felt a little distance below the costal margin.

Renal symptoms are not prominent, though the *amount* of urine passed is often above the normal despite the febrile movement. It may be below, though rarely, while in still other cases it is about normal; and *retention* on the one hand and *incontinence* on the other have been observed. *Albuminuria* is sometimes met with, and rarely glycosuria.

Arthritis is not uncommon, particularly in the severer cases.

Kernig's Sign.—In 1884 Kernig first pointed out the impossibility of obtaining complete extension of the leg on the thigh when the patient is *sitting* and the thigh is flexed at a right angle to the trunk. The sign is produced by irritation of the meninges of the lower portion of the spinal cord and of the nerve-roots that constitute the cauda equina, Roglet thinks that one cause for this sign is intraventricular pressure.¹ Under this irritation, increased by the stretching effect of the sitting posture, the tonicity of the flexor muscles of the leg is increased, and as a consequence complete extension of the leg becomes impossible. The contracture disappears when the patient assumes the dorsal decubitus. If the patient cannot be propped up in bed, the thigh may be flexed upon the abdomen, when, if meningitis be present, complete extension of the leg will be prevented by contraction of the flexor muscles. Head's² statistics, embracing 156 cases, show that Kernig's sign is present in 84 per cent. of the cases of meningitis. It is not confined to cerebro-spinal meningitis, but is present in all meningeal affections. The time of its appearance is variable; hence, in order to be certain that the sign is not present, it should be looked for repeatedly. Again, the time of its disappearance varies; it may disappear during the preagonal period. The value of the sign is real, but its absence does not justify the exclusion of meningitis, while it may be present in other diseases (typhoid, tetanus). Herrick³ points out that from its persistence into convalescence it may be utilized to make a retrospective diagnosis.

Macewen's sign (*vide* Tuberculous meningitis, p. 253), a hollow note on percussing over the inferior frontal or parietal bone, is an indication of fluid in the ventricle, but is not always present.

Brudzinski's Sign.—On attempting to bend the neck flexure movements in the ankle, knee, and hip-joints occur (identical reflex). Another, though less constant, sign is produced by passive flexion of one leg, which causes the fellow limb to draw up, and so remain (contralateral reflex).

Complications.—Many of these have already been mentioned in the portrayal of the symptoms—*e. g.*, destructive inflammations of the eye

¹ P. Roglet, *Gaz. heb. de Méd. et de Chir.*, July 15, 1900.

² *St. Paul Med. Jour.*, Sept., 1900.

³ *Amer. Jour. Med. Sci.*, July, 1899.

and ear and the paralyses of the cranial nerves. The purulent inflammations of the serous sacs which were referred to in discussing the pathology (pleurisy and pericarditis) are among associated conditions, and secondary bronchitis is common. *Pneumonia* (lobar and lobular) is a frequent complication. Endocardial murmurs are common, but pericardial friction is less so. *Hemorrhagic nephritis* is a rare complication.

Special and Atypical Forms.—(1) **Mild or Rudimentary.**—In this type the characteristic signs are either undeveloped or wanting, and the diagnosis is possible only during the prevalence of epidemics, which furnish typical cases. The most constant and significant symptoms are severe headache, languor, vertigo, nausea, and occasionally vomiting. Fever and contraction of cervical muscles are absent, as a rule. The duration is brief, rarely exceeding three or four days.

(2) **The Abortive Form.**—Here the initial symptoms are severe, but after two or three days they rapidly subside, leaving the patient convalescent. The disease is cut short by the acquisition of immunity, and not as the result of medical interference.

(3) **Intermittent Form.**—In this variety the symptoms, however intense, remit or almost wholly intermit every day or second day; these remissions are followed by a decided exacerbation or recurrence of the distressing features of the disease. Intermissions often occur at an advanced stage. There is not observed the strict periodicity that is seen in malaria. Neither is the malarial plasmodium found in the blood.

(4) **Typhoid Form.**—In certain cases the special features are characteristic of the "typhoid state," with protracted course.

(5) **Fulminant or Apoplectic Form.**—The symptoms characterizing this most malignant type of the affection are rather inconstant. There may be severe chill, loss of consciousness, followed by deep coma and death, the whole course occupying the space of a few hours only. I saw two such cases in the same family: the first, a girl of five years, was stricken at 2 P. M. and died at 9 P. M.; the other, a boy of seven years, was taken ill on the following day about the same hour, and died at 10 P. M. Other instances pursue a somewhat slower course, though manifesting the most striking malignancy. These begin with intense chills, violent headache, vomiting, early stupor, great prostration, contraction of muscles of the neck, moderate fever, and a feeble, progressively slowing pulse until it sometimes reaches 50 or even 40 beats per minute. The eruption, when it appears, takes the form of purpura. This form is most apt to be met with early in an epidemic, and with few exceptions proves fatal.

(6) Schlesinger¹ states that epidemic cerebrospinal meningitis affects a senile type in elderly subjects, with little tendency to fever, or opisthotonos.

Diagnosis.—The most important symptoms for diagnosis are the abrupt onset; intense pains (cervico-occipital and lumbar); prostration; vomiting; vertigo; somnolence, alternating with local or general tonic or clonic convulsions; delirium (often sportive in type); tonic contraction of the muscles of the neck, extending to the back; marked hyperesthesia; a slow, followed by a more rapid, though variable, pulse; irregular temperature-curve; and certain eruptions (petechial, herpetic).

Lumbar Puncture.—The value of Quincke's lumbar puncture as a means of diagnosis is absolute. It alone can render the diagnosis certain in many cases, and is a harmless measure, if rigid asepsis be

¹ *Jour. Amer. Med. Assoc.*, October 16, 1909.

observed. The patient is placed upon the right side, with the left knee well drawn up; a fine needle, three inches in length, and carefully guarded by the index finger of the operator, is introduced between the third and fourth lumbar vertebræ "one-half inch to the right of the median line" (Mallory and Wright), and directed slightly inward and upward. The forefinger of the disengaged hand must be used as a guide, and the site should be anesthetized by the application of a local freezing-mixture. The needle should enter the canal at a depth of two or three centimeters in children and four to six centimeters in the adult. If the fluid does not flow, the dura has probably not been penetrated, and *no form of suction* upon the needle should be attempted; the fluid should be allowed to fall drop by drop into a sterile test-tube held aslant. From five to ten cubic centimeters of the usually cloudy exudate should be withdrawn and subjected to a microscopic and bacteriologic examination. Lorgo¹ insists that lumbar puncture must be repeated if the result of the procedure is at first negative. The fluid is said to be clear in tuberculous meningitis. If the presence of the diplococcus intracellularis in the nasal secretion can be shown, lumbar puncture is unnecessary. The precipitin reaction permits one to make a diagnosis, and sometimes with perfectly clear cerebro-spinal fluid (Vincent and Bellot²).

Differential Diagnosis.—(1) *Tuberculous Meningitis*.—In this affection there is usually a tuberculous history—either personal or family—with prodromes extending over many days (occasional vomiting, unnatural peevishness, constipation), unlike the sudden onset of meningitis. The retraction of the abdomen is greater, while the arching of the neck, the general myalgic pains, and the hyperesthesia are less; the herpetic and petechial eruptions are rare in tuberculous and common in cerebro-spinal meningitis. Cheyne-Stokes breathing and the well-marked changes of pulse belong peculiarly to the tubercular form. By the aid of the ophthalmoscope choroidal tubercles may sometimes be detected.

Hand³ urges lumbar puncture in the diagnosis of tuberculous meningitis. He found polymorphonuclear leukocytes in excess of the forms wherever tubercle bacilli were absent.

(2) *Pneumonia*.—This affection may be complicated with a meningitis that affects chiefly the cerebral cortex. Hence, while there will be motor spasm (more or less localized) and tremors, there will also be less retraction of the head and less myalgic pain than in cerebro-spinal meningitis. Again, pneumonia precedes the development of the meningeal symptoms.

(3) *Typhoid Fever*.—The cerebral type of this affection may simulate closely meningitis. In both may be observed fever, delirium, somnolence, retraction of the neck, spasm, tremor, and profound prostration. The mode of onset, however, is different, being slower in typhoid and unaccompanied by vomiting, muscular spasm, or hyperesthesia. In typhoid there is also the characteristic mental dulness; the fever is higher, with a typical fever-curve; the roseate eruption and sero-reaction are characteristic, and there is greater enlargement of the spleen.

Sequelæ.—The leading sequelæ are permanent blindness (due to optic neuritis with atrophy) and deafness, which sometimes terminates in

¹ *Polyclinico*, March, 1901; Saunders' *Year-Book*, 1902.

² *Bulletin Académie de Médecine*, vol. lxi, p. 326.

³ *Phila. Med. Jour.*, Aug. 30, 1902.

deaf-mutism; and in many cases headache outlasts the disease for months. Chronic hydrocephalus and mental enfeeblement are not rare sequels (Ziemssen). Various local paralyses are observed, probably due to certain peripheral lesions (neuritis and perineuritis).

Immunity.—Permanent immunity is rarely conferred by the occurrence of cerebro-spinal meningitis, *relapses* being common, and *second* (recurrent) attacks having been occasionally observed.

Duration and Prognosis.—In very mild forms the duration is from one to four or five days. The most malignant type runs an even shorter course, when, as is the rule, it terminates fatally. If recovery ensues, it is after a long, serious, and protean illness. The *abortive form* is necessarily of brief duration. In the ordinary type convalescence usually sets in at the end of one or two weeks, but a slow convalescence, hindered by numerous complications and sequelæ, is the rule.

Apart from the *fulminant form*, which nearly always proves fatal, the severity of the infection may be appreciated by noting the degree of fever and the intensity of the nervous symptoms, especially the vomiting, coma, headache, opisthotonos, character of the respirations, etc. *Complications* may likewise affect the prognosis, pneumonia, and suppurative inflammations of the pleura or pericardium, rendering it particularly grave. In *children* under two years the disease is very fatal, this period giving the highest mortality-rate; between two and five and after thirty years it is a more serious disease than during young adult life. The death-rate of cerebro-spinal fever varies greatly in different epidemics, ranging from 25 per cent. in the mildest to 80 per cent. in the severest.

Prophylaxis.—Disinfection of the nasopharynx, the expectoration, conjunctival secretions, and the urine is recommended with a view to destroying the specific poison. Meningococcus carriers must be discovered and treated. Isolation is to be carried out. Persons in any manner exposed and suffering from diseased conditions of the respiratory apparatus or pharynx should receive prompt and active treatment.

General Management.—The sick-room must be quiet and somewhat dark. All excitement is to be avoided; the patient must not be allowed to leave his bed until convalescence is firmly established.

The *diet* should be composed of nutritious liquids, such as milk and animal broths, etc., and as soon as convalescence begins the dietary should be increased by the addition of semisolid substances (rice, eggs, milk-toast, etc.), and, finally, the more easily digestible solids. The period of convalescence may be much abridged by systematic feeding.

Medicinal Treatment.—Individual cases are to be treated according to the special indications presented. I regard it as extremely improbable that any case of this affection has been benefited by venesection.

Among medicinal agents narcotics are the most useful. Morphin hypodermically affords relief from intense headache, myalgic pains, muscular contraction, and other nervous symptoms in some cases. If the respirations be irregular, atropin may be combined with the opiate; and if the heart threatens to fail, strychnin may be administered. Should morphin fail, the bromids and chloral (the latter in small doses) are to be employed. In young children we must rely upon the bromids rather than the opiates.

Flexner and Jobling¹ present a report on 393 patients treated with Flexner's curative serum. Of these, 295, or 75 per cent., recovered and 98, or 25 per cent., died. The serum is injected directly into the sub-arachnoid space after the withdrawal of an equal amount of cerebro-spinal fluid by means of lumbar puncture. The injections should be repeated daily for three or four days. When the Macewen percussion-note, however slight, is obtained, Koplik proceeds to puncture. Wasserman² reports 102 cases treated with antimeningococcus serum; it had a curative effect when injected early in the disease (dose, 5 to 10 c.c., repeated two or three times a day). McKenzie and Martin³ have introduced an autogenous serum; they withdraw blood serum of a patient suffering from meningitis and inject it into the spinal canal of the same or another meningitis patient. Such a serum is an actively bactericidal fluid.

For the tonic contraction of the muscles and violent cerebral symptoms, cannabis indica should be tried. Convulsions call for hot baths (105° F.) or ether inhalations. Mercury has been, and still is, advocated (mercuric chlorid, gr. $\frac{1}{24}$ —0.002, every four hours to an adult; calomel, gr. $\frac{1}{12}$ — $\frac{1}{16}$ —0.005—0.004, every four hours to children). Belladonna and ergot have been employed in the early stages to diminish the congestion of the cerebro-spinal capillaries. Antipyrin and acetanilid, being depressants, are objectionable.

Stimulants are required if signs of heart-exhaustion appear. They may be freely exhibited in accordance with the customary rules.

After effusion of the exudate has taken place, the narcotics are to be replaced by agents that promote absorption, as potassium iodid.

The **local means** are also important. When tub-baths are not available, cold should be used locally, since it is both of value and very grateful to the patient. An ice-bag is to be put on the head, and, if possible, long ice-bags placed along the spine. In rare cases of sthenic type we may employ small blisters at the nape of the neck or over the mastoids; they are useful during the stage of effusion. In the usual form of the disease it is better to apply the thermocautery lightly over the mastoid region. A small amount of blood may be withdrawn by means of leeches or by a few wet cups placed behind the ears. Quincke's lumbar puncture and laminectomy with free drainage have been practised, and lumbar puncture should, if necessary, be repeated, but only in case benefit follows first puncture. The principal effect is the relief of the pressure upon the central nervous system. On the other hand, Koch states that the puncture is of questionable therapeutic value.

Convalescence is prolonged, and requires to be diligently and judiciously treated. We must rely upon the generally accepted tonics—iron, cod-liver oil, arsenic, and strychnin; the potassium iodid and the mercury also being continued for their influence in promoting the absorption of the exudate. Special attention is, however, to be paid to the hygienic management of this period. An abundance of fresh air, sunshine, and easily assimilable food must be furnished at all hazards, and electricity and massage, judiciously employed, will hasten recovery.

LOBAR PNEUMONIA.

(*Croupous or Fibrinous Pneumonia; Pneumonitis; Lung Fever.*)

Definition.—An acute infectious disease caused by the *Micrococcus lanceolatus*, which produces a specific inflammation of the parenchyma of the lung and marked constitutional disturbances—chill, extreme prostration, and fever which terminates by crisis. There are different forms of lobar pneumonia, as primary lobar pneumonia, secondary lobar pneumonia, and pneumonia with the formation of new connective tissue.

Pathology.—Usually the lesions are confined to the whole of one lobe; less frequently to the whole of one lung, and rarely to parts of both lungs. From Jürgensen's analysis of 6666 cases the following statement, showing the different situations of the lesions and their relative frequency, was taken: Right lung, about 54 per cent.; left lung, about 38 per cent.; and both lungs, about 8 per cent. In the right lung the lower lobe was involved in 22 per cent., the upper in 12 per cent., the middle in nearly 2 per cent., and the whole lung in about 9 per cent. In the left lung the lower lobe was involved in about 23 per cent., the upper in about 7 per cent., and the whole lung in about 8 per cent. The disease involves whole segments of the lungs, and these may embrace more than one lobe.

The lesions of pneumonia are divisible into three stages: (a) Stage of congestion or engorgement; (b) Red hepatization (consolidation); and (c) Gray hepatization.

(a) **Stage of Engorgement.**—The part or parts implicated are of a dark-red color, and firmer to the feel, but less resilient and crepitant, than normal. The cut section drips a blood-stained serum, and dark blood exudes from the distended capillaries. The air-cells do not collapse, though they are not solid, since excised pieces float; but the weight of the lung-tissue is much increased. Collapsed portions may be observed which may readily be insufflated from the bronchus, and areas of extravasation may occasionally be noted near the pulmonary pleura.

On *microscopic examination* the alveolar epithelium is seen to be swollen, the capillaries greatly distended, and the air-cells containing alveolar epithelial cells, red corpuscles, and a few leukocytes. Similar elements occupy the small bronchi.

(b) **Red Hepatization.**—The affected tissue is solid, airless, and firm, resembling, as the term indicates, liver-tissue. It is reddish brown (mahogany) in color, presenting a dry, mottled appearance, and when, as is usual, an entire lobe is involved, it is more voluminous than normal and its surface is often furrowed by the impress of the ribs. Being airless, the affected portion does not crepitate, and its weight and specific gravity are increased. It cannot be inflated; is extremely friable, and its lacerated surface presents a finely granular aspect, this latter appearance being due to the minute plugs of inflammatory matter (fibrin) which fill the air-spaces. The air-passages and small bronchi are distended with similar material, and granular masses can be removed from the air-cells of a cut or lacerated surface by carefully scraping the latter. If death

takes place during this stage, the ante-mortem, dry, inflammatory exudate soon softens, and may flow from the cut section as a grumous, viscid fluid; the consolidated tissue sinks rapidly in water. The pulmonary pleura is covered with a fine sheet of fibrin, and in cases complicated by marked pleurisy the fibrinous, inflammatory exudate forms a thick coating upon the pleural membrane, and the sac may contain liquid effusion.

Microscopic examination shows the air-spaces filled with clotted fibrin, in whose meshes are held red blood-corpuscles, pus-cells, and changed alveolar epithelium. The interlobular connective tissue may be infiltrated with leukocytes and fibrillated fibrin, but the blood-vessels in the walls of the alveoli remain pervious. The pneumococci (*micrococci lanceolati*), less frequently also streptococci and staphylococci, are detectable.

(c) **Gray Hepatization.**—In this stage the fibrinous exudation becomes decolorized, the surface at first resembling granite in color, and later appearing uniformly gray. Associated with this change, and following it, there is fatty and granular degeneration of the inflammatory exudate, in consequence of which the latter becomes moist and soft. The exudate loses its granular character, while at the same time the friability of the lung-tissue is further increased, and from the surface of the cut section there flows usually a grayish-white or yellowish-white purulent liquid. Not less than one-half of the fatal cases die in the early part of this stage. The pleura is usually covered with a fine fibrinous exudation.

Microscopic examination shows the air-cells stuffed with leukocytes, while the other histologic elements (fibrin, red blood-cells) have disappeared; and with the full development of gray hepatization resolution usually commences. The exudate is now softened into a liquid material with disintegration of cellular elements, and is absorbed by the lymphatics. *Resolution* usually corresponds in time with the occurrence of the crisis, though it may begin later. Pratt¹ found larger phagocytic cells in all stages of the disease; it is likely that they play an important part in resolution. Among unfavorable terminations are—

(1) **Purulent Infiltration.**—Here the lung-tissue becomes very soft, friable, and is bathed in purulent material; and microscopic observation shows the pus-cells densely infiltrating the interalveolar tissue and filling the air-spaces as well. Necrosis of the lung-texture may occur, producing abscess.

(2) **Abscess.**—This is to be attributed to subsequent infection by streptococci, and hence is a complicating lesion. The abscesses vary in size within the widest limits, most frequently being situated near the base of the lung. In most instances the abscess-cavity has a fistulous connection with a bronchus, but occasionally the abscesses become encapsulated in fibrous tissue, their contents undergoing first caseous, and then calcareous degeneration. When multiple, they sometimes coalesce, forming large abscesses.

(3) **Gangrene** may rarely follow, but is due to a specific cause.

(4) **Induration.**—A. Fränkel states that in a few instances (about 1 per cent.) pneumonia ends in induration, and is found upon section to be smooth and its tissue resistant (*vide* Chronic Interstitial Pneumonia).

(5) Pneumonia, particularly of the apex, may terminate in phthisis. Tubercular infection commonly occurs in unresolved pneumonias.

¹ W. H. Welch's *Festschrift*, p. 265.

Changes in Other Viscera.—The *heart* often appears pale and is flabby, but upon microscopic examination the muscular cell-fibers of the organ are not found to be degenerated, except in rare and usually protracted cases. The cardiac chambers, particularly the right, are distended with firm, tough clots, which are usually removable *en masse* from the great vessels in the form of arboreal casts. The blood tends to coagulate, owing to the fact that its fibrinous elements are vastly increased, and also on account of auto-agglutination of the red cells (Flexner).

Pericarditis occurs in about 5 per cent. of the cases, and is relatively more frequent in right-sided or double pneumonia. *Endocarditis* is more common, especially the ulcerative form—in 11 out of 100 autopsies (Osler). With malignant endocarditis the lesions of meningitis are often combined, but as a separate complication the latter is rare.

The *spleen* is congested, moderately enlarged, and softened, and the *liver* is likewise hyperemic and somewhat swollen. In the *kidneys* are found the lesions of parenchymatous inflammation, and with remarkable frequency also those of chronic interstitial inflammation. A catarrhal state of the gastro-intestinal mucosa (often with jaundice) is common; and a frequent complicating change is croupous inflammation of the colon.

When the infection is caused by the Friedländer's bacillus the diseased portions of the lung are increased in volume, and multiple foci may be formed throughout one lobe (Kokawa). The cut section is characterized by a slippery sensation to touch owing to the presence of a large amount of mucus, especially in the early stages. Swelling, proliferation, desquamation, and necrosis of the epithelium is observed. The fibrino-hemorrhagic exudate is not great, the large, emigrated leukocytes, and the epithelial cells forming the principal constituents of the exudate in the later stages. The bacilli are taken up by the epithelial cells and leukocytes, which swell up and develop vacuoles. Other infections may be caused by the pneumobacillus—pleuritis, endocarditis, pericarditis, abscesses, otitis media, and osteomyelitis.

Etiology.—**Bacteriology.**—The generally accepted specific cause of pneumonia is the *Micrococcus lanceolatus* of Fränkel. It is a lance-shaped (slightly elliptic) coccus, united in pairs, when typical has the shape of two cartridges placed end to end, is surrounded by a pale capsule, and is present occasionally in the nose, Eustachian tubes, and larynx of healthy individuals. Netter found it in 20 per cent. of the specimens of buccal secretion taken from well persons, and "it is the migration of these ever-present germs into the pulmonary alveoli which causes pneumonia" (Wells). It is present in about 80 per cent. of all instances of pneumonia, and in persons who have had the disease it is detectable for many months or even years. It is generally present in pure culture, but may be associated with pyogenic organisms. It is probable that Friedländer's bacillus (discovered in 1883) and other micro-organisms (Eberth's bacillus, streptococcus of erysipelas, bacillus pestis) may also have the power to cause the disease; and Wassermann¹ suggests that specific forms of pneumonia may coexist in the same individual, as, for example, lobar pneumonia and influenzal pneumonia. The organism grows upon all the culture-media except potato, between the temperatures of 24° and 42° C. (McFarland). The *micrococcus lanceolatus* (Fig. 10) can be readily demonstrated in the sputum by

¹ *Deutsch. med. Woch.*, Leipzig, Nov. 23, 1893.

treating a fixed cover-slip preparation with glacial acetic acid which is allowed to drain off and is replaced (without washing in water) by anilin oil-gentian violet solution; this is to be poured off and renewed two or three times.

The Pneumococcus in Other Diseases.—It has been found in pure culture in pleuritis (including empyema), pericarditis, meningitis, peritonitis, endocarditis, synovitis, bronchopneumonia (principally in adults), acute abscess, and other conditions.

The mode of infection is by inhalation, although there may be other portals of entry. The first effects of the germ are local—in the lung, though it may reach more distant organs. To the widespread distribution of the pneumococcus is due, in part, the septicemic process sometimes observed. The toxins of the *micrococcus lanceolatus* also become diffused throughout the system, producing a general disturbance (*toxemia*). *Secondary infection* with other specific organisms (streptococci, staphylococci, colon bacillus) commonly occurs in the various organs of the body.

Predisposing Causes.—(1) **Endemic Influence.**—That epidemics of pneumonia, often of serious type, may occur in solitary buildings (barracks,

FIG. 10.—*Diplococcus pneumoniae*, from the heart's blood of a rabbit; $\times 1000$ (Fränkel and Pfeiffer).

tenement-houses, institutions, etc.) cannot be successfully denied, and we may attribute these outbreaks to defects in the local sanitary conditions.

(2) **Epidemic Influence.**—From time to time pneumonia prevails epidemically. Epidemics are caused by an increased virulence of the organism. Pneumonia may also originate in the endemic form in tenement-houses and institutions, and increase in its scope until it assumes an epidemic character. House epidemics occur, and in the winter of 1894 I saw, with Dr. W. K. Mattern, of Philadelphia, 3 cases develop in rapid succession in one family. A Sister of Charity, after nursing

two of the patients faithfully, also died of the disease. It is possible that the house-epidemic form may spread by *contagion*. An instructive epidemic is reported by W. B. Rodman, who states that 118 cases of pneumonia, with 25 deaths, occurred in a prison population of 735. B. Robinson insists upon his view that pneumonia is contagious.

(3) **Geographic Distribution.**—Pneumonia may be said to be an almost universally distributed affection. Climate, *per se*, does not exercise a notable influence. Delafield, however, points out the fact that in the United States the disease is of more frequent occurrence in the South than in the North.

(4) **Season.**—Of 5905 cases collected by Seitz in Munich, 36.8 per cent. occurred in the spring, 32 per cent. in winter, 15.7 per cent. in autumn, and 15.3 per cent. in the summer. In London most cases appear between the end of March and the end of June (Herringsham). My own analysis of the monthly mortality list covering the decade from 1894 to 1903 inclusive, for Philadelphia, gave the following numerical order: January, 4,210; February, 3,717; March, 3,496; April, 3,039; December, 2,860; May, 2,238; November, 1,936; October, 1,269; June, 1,165; July, 913; September, 826; August, 800.¹ The period of greatest frequency will be sometimes found to correspond in time with the period of the greatest vicissitudes of temperature and humidity. Exposure to cold is incapable, *per se*, of giving rise to pneumonia.

(5) **"Catching cold"** is often followed by pneumonia, but frequently there is no such history. The so-called "cold" is a predisposing cause, rendering the respiratory passages more than ordinarily susceptible to pneumonic infection. Such facts as these also explain why pneumonia occurs with undue frequency in persons following certain occupations.

(6) **Traumatism.**—Following injuries, especially of the chest, pneumonia occurs quite frequently. Contusions of the thorax lower the vital power and resistance of the tissues.

(7) **Age.**—Lobar pneumonia is common at all periods of life, but before two years of age it is comparatively infrequent. Between the ages of twenty and forty susceptibility is increased, and again after the sixtieth year of life it augments rapidly.

(8) **Sex.**—Males are more commonly attacked than females, the discrepancy in the relative number of cases being greatest from the twentieth to the fiftieth years of age, and being due to the more frequent abuse of alcohol by men.

(9) **Race.**—The negro, American Indian, and the Esquimaux are more susceptible to pneumonia than the white race.

(10) **Unhygienic Surroundings.**—The disease is more frequent among the lower than the higher classes—a fact due to the improved hygienic environment of the latter.

(11) **Circumstances Connected with Individuals.**—The alcoholic is especially prone to this disease, any or all habits that tend to depress the nervous system acting as predisposing causes. The increasing incidence of pneumonia is probably due in a measure to the recognized increase in frequency of the various forms of degeneration of the viscera, particularly of the heart and kidneys. Certain chronic diseases, therefore (chronic Bright's disease, organic heart-affections, carcinoma, diabetes,

¹ "Meteorologic Conditions in the Causation of Lobar Pneumonia," *Amer. Med.*, Sept. 1, 1904.

etc.), exert an influence. Emigrants would seem to be more susceptible than persons who have become acclimated.

(12) **Prior Attacks.**—One attack undoubtedly leaves the system more susceptible to the disease, so that repeated attacks—ten or more—may occur in the same individual.

(13) There has been noted a marked increase in the number of cases of lobar pneumonia during the past two decades, due to the prevalence of influenza. Wells has shown by statistical facts that the incidence of the disease has steadily increased during the last century.

Immunity.—The results of the investigations of Behring and Kitasato with the blood-serum of animals which had been immunized against tetanus and diphtheria led Drs. G. and F. Klemperer to experiment upon the lower animals with Fränkel's diplococcus. They found that the rabbit could be rendered immune by intravenous or subcutaneous injections of large amounts of the fluid bouillon-cultures or of the glycerin-extract. From 10 to 20 c.c. of serum taken from a non-receptive animal were injected into the veins of an animal that was suffering from typical pneumonia (artificially produced), whereupon the symptoms subsided rapidly and the animal entered upon a speedy recovery. The same serum, used in a similar manner upon healthy receptive animals, rendered them non-receptive.

Clinical History.—*Prodromes* are rare, and when present consist of a slight general indisposition, lasting a day or more. Rarely, there is cough, thoracic oppression, and slight chest-pains (simple bronchitis), that may or may not be connected with the pneumonic process. Here invasion may be marked by sudden, great thoracic oppression or by a gradual development of the local and general symptoms without rigor.

Usually the *invasion* is *very abrupt*, and marked by a severe *rigor*, which has a duration of from half an hour to an hour, during which period the patient feels most uncomfortable, and is, indeed, very ill. The initial chill may occur at any hour of the day or night, the *fever* rising immediately and rapidly, and the temperature often mounting to 104° F. (40° C.) or even higher in the course of a few hours. The *skin* becomes harsh and dry, the face flushed, and the cheek on the side affected often shows a circumscribed deep-red spot. *Prostration* is pronounced, and headache and other nervous disturbances (restlessness, delirium) accompany and follow the ushering-in symptoms.

The *thoracic symptoms* follow closely upon the termination of the chill. Inspiration, particularly if deep, causes a stabbing *pain* in the affected side; the respirations are hurried, somewhat jerking and shallow (panting), while the pain persists, and later *dyspnea* may become marked, with accelerated breathing. *Cough* sets in early, and is dry and painful during the first day or even longer, and may be attended with expectoration, which generally presents a characteristic *rusty* or *blood-stained appearance*. The *physical signs* rarely appear before the end of the first day, and sometimes as late as the third (central pneumonia); in the latter form the local symptoms, as cough, dyspnea, and sometimes pain, are either wanting or feebly expressed during the first three or four days, and the clinical picture is composed of the general features only.

Anorexia is usually complete; *thirst* is excessive, and commonly there is *vomiting* at the onset, the bowels being generally constipated, though diarrhea may not infrequently be present. The patient in most instances

lies upon the affected side until the pain has in great part subsided, and then he is apt to assume the dorsal position, exposing to full view an *anxious countenance*, with a characteristic *flush* upon the cheek, while the *alæ nasi* are seen to dilate forcibly during inspiration. Very frequently *herpes* on the lips or nose appears about this time, and forms a valuable diagnostic symptom. The nocturnal remissions are slight, the temperature being of the continued type, and the fever continues high— 104° to 105° F. (40.5° C.)—for from five to ten days, and generally terminates by crisis. The pulse is somewhat quickened, but the *pulse-respiration* ratio is not maintained. The other general features last until the crisis occurs, or even increase in severity, but do not outlast this period; many of the local symptoms, however, and particularly pain, are greatly improved before the crisis is reached.

As will be seen hereafter, the general course of pneumonia is modified by a variety of interfering conditions that have relation to complications, individual circumstances, severity of the type, etc. In the instances in which the crisis is reached convalescence is rapidly established. The crisis may be accompanied by special symptoms, as copious sweating or diarrhea.

Leading Symptoms in Detail.—Local or Respiratory Symptoms.—Increased frequency of the respirations is a characteristic symptom, the rate varying from 40 to 60 per minute in adults, and in children from 60 to 90 or more. It is panting in character, particularly when pneumonia occurs in old subjects, and both inspiration and expiration are brief, though sometimes separated by a rather long pause. Expiration is usually accompanied by an audible “grunt,” indicating great oppression, and while actual dyspnea is a frequent symptom, it may be absent or as the case progresses may become either increased or greatly diminished according to the severity of the type.

The *chief causes* of the rapid and labored breathing are the involvement of a large portion of the lung, associated general bronchitis, pericarditis or extensive pleurisy, cardiac failure, collateral congestion with edema, fever, and the intense pain in the side.

The *pulse-respiration ratio* is disturbed, the relation now being 1 to 2, or even 1 to 1.5, instead of 1 to 4, as in health (see Fig. 11).

Pain in the affected side is in most cases developed within a few hours after the initial chill, and after lasting two or three days gradually disappears. It is stabbing in character, and usually referred to the region immediately below the nipple or to the axilla, and rarely to other points (abdomen, flank—the so-called *abdominal symptom*). In most instances it is not severe until greatly intensified by the cough, which always aggravates this symptom, as does deep inspiration. The pain is due to implication of the pleura covering the inflamed lung, and may be entirely absent, especially in the aged and those showing marked toxemia.

The *cough*, like the chest-pain and respiration, is somewhat characteristic, being frequent, short, dry, and voluntarily repressed, because it is attended with increased suffering. Yet there are cases that run their entire course without cough—*e. g.*, in the aged and in drunkards.

The Sputum.—At first mucoid and frothy, it soon becomes of a characteristic *rusty* color. It consists of a frothy, fluid mucus containing an abundance of small viscid masses of a yellowish- or reddish-brown

color, from admixture of blood. The chief peculiarity of the sputum in fully developed cases is its *viscosity* and *tenacity*, often adhering to the receptacle even though the latter be inverted; owing to its adhesive quality it is ejected from the mouth with considerable difficulty by the patient. About the time of the crisis the sputum usually becomes more abundant, distinctly purulent, and its expulsion easy, but rarely it may be absent after the crisis. In severe types of the disease it may, at the outset, consist largely of pure blood, and in adynamic forms it is often thinner and darker in color (*prune-juice*). There are cases in which there is an abundance of muco-purulent expectoration when extensive associated bronchitis occurs, and, on the other hand, instances are met with in which nothing is expectorated save a little light-colored mucus. In old persons or in those previously enfeebled there may be no expectoration whatsoever. The amount is therefore exceedingly variable.

Under the microscope the sputum is seen to contain red blood-corpuscles, alveolar epithelium, the *Micrococcus lanceolatus* (usually with other micro-organisms), pus-corpuscles, and small fibrinous casts.

General Features.—The Fever.—As I have already stated, the fever rises rapidly during the initial chill, so that in eight to twelve hours the temperature reaches 104° or 105° F. (40.5° C.). It then remains high until the crisis, pursuing the continued type, with nocturnal remissions amounting to a degree or over, while the daily fluctuations correspond with the normal, except that they are now somewhat exaggerated. In children the rigor is almost always replaced by convulsions. The temperature has a lower average range in persons previously debilitated, in old people, and in drunkards, than in healthy adults and children. During the febrile period there may be observed a pronounced fall of temperature—pseudo-crisis—but the temperature again rises to its former height. This may occur quite early, though more often it precedes the true crisis by a day or two; and rarely it may take place repeatedly, and the temperature-curve bear a strong resemblance to the remittent or even the intermittent type, regardless of any malarial infection. The temperature may be unusually high, 106° F. (41.1° C.) or even 107° F. (41.6° C.), these striking elevations sometimes preceding the crisis (*perturbatio critica*), and hyperpyrexia is often the signal of approaching dissolution. It is especially characteristic of pneumonia, however, that the fever terminates by *crisis*; hence a mere glance at the temperature-chart may serve to complete the diagnosis in doubtful cases (see page 113). The crisis may occur anywhere from the end of the third to the fourteenth day, but in the majority of instances it is on the seventh or the ninth day. The temperature usually falls during the night, and the drop is accompanied by copious perspiration, so that by the following morning the thermometer is found to register at the normal, or more often a subnormal, point (96°–95° F.—35° C.).

The *duration* of the period of decline is usually from eight to twelve hours. It may be much shorter, but more commonly it is longer, or by lysis. The latter mode of termination is often due to some complication. A gradual fall of the temperature in this disease is more common at present than formerly. After the crisis the temperature may remain subnormal, or there may occur a slight postcritical rise; the respiration and pulse-rate quickly return to the normal.

Circulatory Symptoms.—The average pulse-rate in typical cases is

FIG. 11.—Chart of a case of lobar pneumonia with favorable course. A. T., aged thirty-two years; lower right lobe affected. Black, temperature; red, pulse; blue, respirations.

about 100 to 108 per minute, and when it exceeds 120 there is just cause for alarm. The rate may be increased either suddenly or gradually, but in any event augmented frequently implies danger. Cardiac failure is generally due to the effect of the pneumotoxin upon the heart, although less commonly also either to previous organic disease of the heart or to some complicating condition (pericarditis, collateral edema), and the period of greatest liability is in the advanced stage of the disease. Vasomotor paresis affecting the splanchnic area is also a factor in causing heart-exhaustion. At first the pulse is small, especially in extensive consolidation; a little later, full and bounding. Dicrotism may be noticeable, and an irregularity in the volume and rhythm of the pulse may be observed; it is an unpropitious sign. In the aged and the weakly a feeble, frequent pulse may be present.

The *blood-pressure* generally begins to fall after three or four days, and when it progresses and exceeds 25 mm. Hg. it is significant and calls for increased stimulation. A prompt fall indicates approaching dissolution, as a rule. Brem¹ states that the first sign of exhaustion is always a fall of the peripheral tension. MacKenzie points out that when the line of blood-pressure, measured in mm. of Hg., falls below that of the pulse-rate, there is danger, and vasomotor stimulants are required.

The *heart-sounds* are clear, and owing to increased tension in the pulmonary vessels the pulmonary second sound is accentuated. This is the state of things throughout in favorable cases. With failure of the right ventricle (a not rare event) there arise the signs of dilatation of this chamber (extension of cardiac dulness to the right, epigastric impulse, a low systolic murmur, shortening of the diastole, or fetal heart-sounds, cyanosis, and indistinctness of the second pulmonary sound). A soft, low-pitched murmur may be audible in the mitral and pulmonary zones.

The *blood-appearances* are somewhat characteristic. There is a leukocytosis varying from 10,000 to 40,000 or more. The researches of Lache² show that leukocytosis is of some value in determining between the crisis and pseudo-crisis, continuing in spite of the fall of temperature, etc., in pseudo-crisis, while it disappears with the true crisis. Stienon³ finds that in the febrile stage the polynuclear forms predominate, but as soon as these diminish the eosinophiles begin to increase. A small percentage of myelocytes may be found. Slight leukocytosis may indicate a mild infection, but, as a rule, it is a bad prognostic sign. Leukopenia occurs in the malignant cases; on the other hand, leukocytosis of high degree, while indicating a severe infection, "it, at the same time, shows a good reaction."⁴ Leukocytosis, however, may be prevented by previous infections (*e. g.*, typhoid) and the use of internal antipyretics. Ludwig Jehle⁵ reports 6 cases of the agglutination of the pneumococcus by the serum of pneumonia patients.

The red corpuscles and hemoglobin remain little changed during the fastigium, but show a marked decrease almost immediately after the actual crisis.⁶ The blood-plates are also increased in number (Hayem). Da Costa has collected 9 cases of phlegmasia alba dolens in pneumonia.

Cerebral Symptoms.—*Headache* sets in early and may be a prominent and persistent feature. In many cases, and particularly in children, the disease is ushered in by convulsions, this symptom occurring more often in the apical than in the basilar form of pneumonia. *Delirium* may come on during the acme of the disease (rarely, it may start as an acute mania), and may assume a maniacal form, but oftener in my experience consciousness has been retained. In the drunkard *delirium tremens* usually develops, and may anticipate the symptoms referable to the lungs; and I fully agree with Osler in stating that it should be an invariable rule, if fever be present, to examine the lungs in delirium tremens. These cases may often be appropriately termed "*walking pneumonia*," since they go about until excitement gives way to a coma that deepens into death. In *adynamic forms* a low, muttering delirium and coma are frequent.

In the so-called *cerebral pneumonia* the nervous phenomena are quite pronounced, and simulate closely cases of cortical meningitis. It is often associated with excessively high fever, except in the aged, when the cerebral symptoms are also well marked, but the fever is moderate. Apical pneumonias are apt to assume the cerebral type, but in my experience this dictum is correct as relating to children only. Double pneumonias are commonly characterized by severe cerebral symptoms.

The Cutaneous Symptoms.—As stated before, herpes is common and its diagnostic importance is considerable. *Naso-labial herpes* is but little less frequent in this disease than in malaria, being present in about one-third of the cases. It usually comes out from the second to the fifth day of the disease, and rarely may appear upon the cheek, lobe of the ear, the genitals, forearm, or upon the mucosa of the tongue. Sweats are not common except at the time of the crisis, when they may be copious. The deep-red circumscribed spot upon one cheek (*mahogany flush*), usually on the side of the affected lung, has already been mentioned. Urticaria has been observed, though rarely.

Digestive System.—The mouth is dry, the tongue has a coating of a yellowish-white color, becoming dry and brown in cases representing a low form, and anorexia and thirst are present. *Vomiting* is not uncommon at the outset, and may be repeated, while constipation is the general rule and diarrhea the frequent exception. Sears and Larrabee¹ in an elaborate analysis of 949 cases found that pain below the costal margin was frequently present, and in several cases appendicitis, especially when the pain was associated with muscle spasm. Splenic enlargement of slight degree can usually be detected on palpation.

Urinary Symptoms.—The urine is febrile, diminished in amount, and high-colored, the urea and uric acid being greatly in excess. On the other hand, the chlorids are, according to the older authors, either diminished in amount or absent during the febrile stage, presumably for the reason that they pass into the inflamed lung-tissue. They are not, however, constantly absent, and sometimes they are not even lessened, in pneumonia; moreover, their disappearance is not peculiar to this disease. The above-mentioned facts justify two important inferences: (1) The absence of chlorids is a symptom of little diagnostic value; and

¹ *The Med. and Surg. Reports of Boston City Hospital*, Twelfth Series, Dec. 1, 1901.

(2) their reappearance in the urine toward the close of pneumonia is of small prognostic worth. Slight (febrile) albuminuria is common.

Physical Signs.—Stage of Congestion.—The density of the lung is increased, but the involved tissue is not consolidated and the pleura is not yet covered with fibrin.

Inspection.—The movements of the affected side (especially if the base be involved) are defective, the degree of expansion being much diminished. In double pneumonia the costal type of breathing, combined with a vigorous play of the abdominal muscles, is observed.

Palpation.—There is a slight increase in the tactile fremitus over the congested area.

Percussion.—The note may be normal, though more often it is briefer, higher-pitched, or even distinctly tympanitic.

Auscultation.—The breath-sounds are weak, and sometimes become broncho-vesicular upon deep inspiration, while over the unaffected lung-tissue they are exaggerated. If, as often happens, inflammatory products due to associated bronchitis occupy the small bronchi, subcrepitant râles may be audible. The crepitant râle, however, is rarely heard until the close of the first stage.

Stage of Consolidation.—Inspection.—There is little or no expansive motion of the chest over the affected area, while upon the unaffected side it is increased. The volume of the thorax on the diseased side is increased, as shown by mensuration, but the intercostal depressions are not effaced.

Palpation renders clearly perceptible the defect or absence of expansion. Vocal fremitus is usually much increased, though in exceptional instances it is diminished or absent—a circumstance which can, as a rule, though not invariably, be attributed to an associated pleurisy with more or less effusion. Frequently a friction-rub is felt before complete consolidation is established.

Percussion.—Varying degrees of dullness are obtained in this stage, and before the lung-tissue becomes thoroughly solidified the note may have a tympanitic quality. After complete consolidation there is usually marked or absolute dullness posteriorly, unchanged by full inspiration, while the note may be more or less tympanitic anteriorly, where the vibrations are more apt to reach the air in the larger bronchi. A sense of resistance is offered to the pleximeter-finger, but not to the same degree as in the case of a pleurisy with effusion. When the latter condition is associated and in massive pneumonia the percussion-note will be flat. Deadness is less marked in old people in whose ribs senile changes have taken place, which render them more resonant, or in cases in which the consolidated areas occupy the central portions of the lung. Above the solidified part Skodaic resonance is usually obtainable.

Auscultation.—Bronchial or tubular breathing is heard, as a rule, over the solidified lung, but it may be absent in consequence of the plugging of the large bronchi with exudate (so-called *massive pneumonia*). Bronchophony is usually obtainable over the portion of the lung affected, though this may also be absent, and for the same reason as in the case of the bronchial breathing: it sometimes takes the form of egophony. Subcrepitant râles, due to associated bronchitis, are sometimes heard with unusual distinctness (owing to the consolidation), and the crepitant râle at the end of inspiration is best heard at the beginning of consolidation, when the pleura receives its coat of fibrin

and while the lung is yet capable of sufficient movement to produce fine pleural friction. A distinct friction-rub may also be heard occasionally.

Stage of Gray Hepatization.—With beginning resolution the solid contents of the air-cells liquefy and are removed, so that air now re-enters the air-cells and permits a consequent increase in the movement of the lung.

Inspection.—The normal expansile movement gradually returns.

Palpation.—Tactile fremitus progressively diminishes.

Percussion.—The dull or tympanitic quality of the note is gradually lost, though the fact must be emphasized that the abnormalities in the note vanish more slowly than the other abnormal physical signs. Some degree of deadness often remains long after apparent recovery.

Auscultation.—With increased movement of the lung there may be a reappearance of the crepitant râle, due to interplay of the pleural surfaces, and the softened exudate in the air-cells gives rise to subcrepitant râles, heard both on inspiration and expiration (*râle redux*), with coarser râles over the bronchi. Bronchial breathing gradually gives place to broncho-vesicular, and the latter in turn to normal, breathing.

The Pneumococcus Septicemia.—The pneumococcus infection may cause severe toxic features and even speedy death without any, or with but little, involvement of the lung-texture. The general *invasion symptoms*, such as the chill, high fever, and nervous symptoms which always predominate, however, are present and persist until death ends all. Death is preceded by signs of cardiac failure, by vasomotor paresis, or, more rarely, by coma. In some of these cases localization of the morbid process may occur in organs other than the lungs, as the cerebral meninges, the endocardium, pericardium, and the pleura. An assured diagnosis in these atypical forms of the pneumococcus infection can be arrived at by a bacteriologic examination of the exudate obtained by aspiration. The pneumococcus can also be demonstrated in blood-cultures, provided that they are made with large quantities of blood.

Complications.—Many of these are due to the primary infection.

Pleurisy is, of necessity, associated in all instances in which the consolidation reaches the pleura. In most cases the presence of the diplococci has been demonstrated. Cases are met with in which the truly pneumonic symptoms are overshadowed by the intensity of the pleuritis and to these the term *pleuropneumonia* has been applied. There is often a copious effusion which is exceedingly rich in fibrin—a circumstance which distinguishes it from other forms of acute pleurisy. There may be the ordinary grade of pleurisy on the side of the pneumonia, and a severe grade on the opposite side which is apt to be purulent. Indeed, empyema has of late been shown to be a frequent complication of pneumonia, and it also occurs as a sequel. A condition that affects its incidence is involvement of the lower right lobe. Lambert and Daly¹ report 5 cases of empyema developing as a complication in lobar pneumonia, which showed a sudden rise of leukocytosis to nearly or more than double the count of the previous day. Its development is accompanied by replacement of ordinary dulness by flatness with great resistance, and by the disappearance of râles and breath-sounds, normal and abnormal. Other characteristic features of empyema are present, but if doubt surround the diagnosis, the needle should be introduced.

¹ *St. Paul Med. Jour.*, Dec., 1902.

There is a prompt rise of fever, the temperature leaping to 103° or 104° F. (39° or 40° C.) quickly, after which it is decidedly remittent in type, but there are no hectic chills. Fistulous connection with a bronchus, however, and the establishment of *empyema necessitatis* are common events, and may be preceded by diurnal chills, sweats, etc.

The occurrence of *septic phenomena* is a certain indication of secondary infection by streptococci. The pus is rarely absorbed and frequently becomes encysted. I saw one instance in which the effusion measured 8 liters, while ordinarily the amount ranges from 2 to 5 liters. Removal of the effusion by aspiration is promptly followed by the disappearance of the fever, but reaccumulation generally occurs.

Finally, if defervescence in pneumonia takes place by lysis or if an irregular fever persists, a residual purulent or sero-fibrinous effusion may be considered as the likely cause. This latter complication is attended by a paroxysmal cough which is excited by movement, and is not usually accompanied by expectoration.

Acute general bronchitis may pre-exist or arise as a complication, and often proves formidable, intensifying the fever and increasing the dyspnea, the tendency to heart-failure, and the cyanosis. The expectoration is freer than in uncomplicated pneumonia, and over the bronchi moist râles intermingled with sibilant and sonorous râles are audible.

Pericarditis.—This is an important and serious complicating affection. According to Chathard, it is oftener synchronous with involvement of the right than of the left lung, hence arises as often by a metastatic process as by direct extension. It was present in 4.66 per cent. of 665 cases and occurred most frequently in young adults. Although generally of the plastic variety, it is not infrequently sero-fibrinous, and rarely the effusion is purulent. The *diagnosis* can be made here as under other conditions, but the complication is often insidious. The occurrence of increased dyspnea, with or without precordial pain, should serve as a signal and lead to a physical examination.

Endocarditis.—This is somewhat more frequent than pericarditis. Preble¹ has well said that endocarditis should always be suspected in a case of pneumonia, which is followed by an irregular temperature not sufficiently accounted for by some other complication, such as empyema. Out of 209 cases of malignant endocarditis collected by Osler, 54 cases occurred in pneumonia. Endocarditis complicates pneumonia in 1 per cent. of all cases and in 5 per cent. of the fatal cases (Preble). It is generally of the malignant type and may attack any valve (the aortic leaflets, however, being most commonly affected). There are no reliable symptomatic indications of this condition. The physical signs must be faithfully and systematically noted. Frequently murmurs are absent; and, on the other hand, the presence of a murmur alone is by no means diagnostic of the complication. Bradycardia is not uncommon, but oftener the pulse is rapid and feeble. The development of septic manifestations, especially irregular fever, chills, and sweats, renders the case highly suspicious, and when in addition there arises distinct evidence of embolic processes the diagnosis becomes highly probable. If, now, the symptoms of meningitis supervene, little doubt remains as to the character of the complications, since meningitis and endocarditis are often combined in pneumonia.

¹ *Amer. Jour. Med. Sci.*, Nov., 1904.

Netter, Weichselbaum, and Bignami have shown that acute endocarditis may be caused directly by the diplococcus of pneumonia.¹

Chronic Endocarditis.—This predisposes to acute endocarditis, both simple and ulcerative, but, independently of the acute form, pneumonia arising in the course of chronic endocarditis is apt to be attended by cardiac failure, with ensuing venous stasis. The murmurs of chronic valvulitis often disappear with the development of pneumonia.

Cardiac clots (ante-mortem) may form, but are rare. They result from weakness of the ventricular wall, especially in the right heart; and are most apt to arise, therefore, in cases in which the preagonal period is much prolonged. Venous thrombosis is rarely seen, and embolism of the larger arteries is a rare complication, the lesions and determining factors being similar to those in typhoid fever. The cerebral embolism, causing aphasia and even hemiplegia, has been observed, but seldom.

Pneumococcus meningitis may be a complication; it differs only in the bacteriologic findings from meningococcus meningitis. Pneumococcus meningitis may also occur independently of lung involvement.

The symptoms are not clearly defined; particularly is this true when it develops during the invasion-period and the basilar meninges are not involved. The presence of intense and persistent headache, rigidity of the nucha, wild delirium, followed by stupor, deepening into profound coma, affords a basis for a probable diagnosis. Its frequent association in the purulent form with ulcerative endocarditis has been pointed out above.

Peripheral neuritis is among the rare complications of this disease.

Parotitis is also sometimes seen, and may cause a fatal termination of the case. I have seen two instances, however, in which this was a complication, and both ended in recovery. It is thought to be associated usually with endocarditis, but not so in my cases.

Arthritis.—A pneumococcic arthritis occurs, but it is rare. The joint is occasionally primarily involved, showing the importance of toxemia (Herrick). It is most prone to develop after the crisis, and is associated with meningitis and endocarditis. The exudate is generally a thick creamy pus, less commonly sero-fibrinous. The changes may be either slight in the acute forms, or extensive and destructive of cartilage and bone, particularly in the more chronic cases. A recognition of the condition demands exploratory aspiration and bacteriologic examination. The mortality-rate is 65 per cent. *Rheumatism* and *otitis media* may be rarely met also, particularly in children.

Gastro-intestinal Complications.—*Croupous gastritis* may rarely intervene, but *croupous colitis* is a more frequent concomitant, giving rise to tympanites and diarrhea, and it may prove a serious condition.

Peritonitis occurs, but with great rarity.

Jaundice may be observed in all types of the affection, though, on the whole, it is more frequent in serious than in mild forms of the disease. It is rarely intense, and has no symptoms as a rule; it is most probably an obstructive (hepatogenous) jaundice. N. V. Pétrov has reported 13 cases complicated with icterus, and in all observed local lesions (mainly catarrhal) of the duodenum and the biliary canals. A catarrhal or suppurative cholecystitis may rarely complicate lobar pneumonia.²

¹ *Practitioner*, London, Aug., 1894.

² "Cholecystitis as a Complication of Lobar Pneumonia, with a Report of Three Cases, and Remarks on Icterus in Pneumonia," by the writer.

Acute nephritis is an important complication, and its recognition is entirely dependent upon the discovery of albumin and casts in the urine. In 20,107 cases of lobar pneumonia, acute nephritis occurred in 263, or 1.3 per cent. (Norris).

Clinical Varieties and Anomalous Types.—(1) **Typhoid Pneumonia.**—This relates to an adynamic, serious type of the disease with *typhoid symptoms*, and not to typhoid fever. It is often secondary to low fevers, to septicemia, diabetes, and chronic nephritis, and is also the variety met with in drunkards and in persons previously enfeebled. The onset is somewhat gradual. The physical signs may be ill defined, but the general features are always striking and characteristic. Prostration is extreme; there are delirium and often stupor; the temperature may or may not be high; while the respirations and pulse are almost always frequent. The skin is dry, and may show a dusky tint or slight jaundice. The tongue is dry, often brown, and vomiting is common; the sputa may be rusty or decidedly hemorrhagic. Splenic enlargement is often clearly perceptible. When recovery ensues convalescence is tedious. Some of the cases belong in the category of atypical pneumonias.

(2) **Epidemic Pneumonia.**—This is often of malignant type. The symptoms exhibit noticeable variations, according to the special etiology and to different epidemics. The pneumonias of *epidemic influenza* are complicated with or preceded by general bronchitis. The heart-power often becomes exhausted early, and then follow congestion and edema of the lungs. The physical signs are often slight.

The so-called *serous pneumonia* often complicates influenza; it is ascribed to streptococcus infection (*streptococcus pneumonia*). Septic phenomena often arise, such as irregular fever and sweats. The physical signs, for a time indefinite, when fully developed resemble those of bronchopneumonia. There may be a tendency to migration from one to the other lung, as in a case under my immediate observation. There may be a late-appearing rusty expectoration, and in some cases the sputa are mucopurulent throughout. The course is often protracted, and the fever may terminate by lysis. In two of my cases the pneumococcus was detected in the sputum in increased numbers. It is said that in mixed infection the micrococcus lanceolatus is abundantly present. In so-called "*larval pneumonia*" the general symptoms are mild and the local signs ill defined. The epidemic outbreaks that occur in institutions, tenement-houses, jails, etc., belong to this variety.

(3) **Latent Pneumonia.**—To this class belong *central pneumonias*. The sputum is to be stained and examined microscopically, when the pneumococcus will be found. The sputum is guminous and rusty, as a rule. When pneumonia arises in the course of emphysema the dilated air-cells are not filled with the exudate; hence dulness is less marked, and true tubular breathing may be absent. Before the crisis occurs consolidation usually advances to the periphery.

(4) **Migratory Pneumonia.**—By this is meant an extension of the specific inflammation to other parts of the lungs. Such extension may prevent the occurrence of the usual crisis, and often occasions an exacerbation of the general pneumonic features.

(5) **Bilious Pneumonia** ("*Malarial Pneumonia*").—In pneumonia occurring in malarial subjects the initial chill is prolonged and the fever paroxysmal or remittent. Jaundice and vomiting are common.

(6) In **children**, the first symptom is often a convulsion. Cerebral symptoms (delirium, stupor, coma) may appear early. The upper lobes of the lungs are frequently involved. Unless the objective indications be examined for, the disease is frequently overlooked. The characteristic sputum is rarely seen in juvenile pneumonia. Crozer Griffith reports 8 cases in which the pain suggested appendicitis.

(7) In **old persons** the initial chill is often absent or replaced by moments of chilliness. There may be nausea and vomiting. Prostration is profound; there is fever, but it does not range high and is irregular. Nervous phenomena, sometimes prominent, are not uncommon, but the local symptoms (cough, expectoration, and pain) are mild or wholly absent. The physical signs are defective owing to impairment of the respiratory movements; dulness on percussion (with a tympanitic quality), tubular breathing, and a few subcrepitant râles may, however, be noted. This affection is a most deceptive one in old people, the cases generally ending fatally after an illness of an apparently mild degree of intensity.

(8) **Abortive pneumonias** last no longer than twenty-four or forty-eight hours. The general features are rigor, high fever, and defervescence by crisis with profuse sweating. The sputum is rarely characteristic, and the physical signs variable; typical tubular breathing is rare, while râles and pleural involvement are common. Bechtold¹ has frequently observed this form affect all the members of a family.

(9) **Terminal Pneumonia.**—Many instances of pneumonia are discovered in the post-mortem room. These arise in advanced cases of chronic pulmonary tuberculosis, organic heart diseases, chronic Bright's disease, diabetes, and the like, and manifest no clinical symptoms other than slight elevation of temperature, an increase in the respirations, and lung consolidation. A fatal termination is the rule in terminal pneumonia.

(10) **Ether-pneumonia.**—Opinions are divided as to the frequency of occurrence of pneumonia after ether-narcosis. The aggregate number of cases from all sources (57,842) gives a percentage of 0.07. My own statistics, embracing 12,842 cases, give a percentage of 0.23.²

The principal causes are—(a) *Season.* According to my investigations, over 80 per cent. of the cases occur during the winter and spring months. The patient is sometimes carried from a heated operating-theatre through a cold corridor to a room or ward with a lower temperature. (b) "Catching cold," or exposure as may obtain during protracted operations. (c) Bronchitis, coryza, and the like present at the time of anesthesia. (d) Dried secretions or incrustations of foreign matter that are loosened by the ether and drawn into the lungs. (e) Abdominal operations give the highest percentage of cases, due, as my studies show, to the more protracted etherization. Mikulicz has shown that ether-pneumonia following these operations is caused by embolism. (f) Graves³ believes that most cases are caused by the lighting up, or aggravating of, pre-existing foci in the lungs.

The *clinical features* are aptly compared with those of secondary pneumonia (*vide p. 130*). The *diagnosis* rests principally upon the typical physical signs. Owing to the extreme latency of the condition, and the danger that the symptoms may be regarded as being septic in nature, I would emphasize the importance of a physical examination of the thorax

¹ *Münch. med. Woch.*, No. 44, 1905. ² "Ether-pneumonia," *Univ. Med. Mag.*, Aug., 1898.

³ *Boston Med. and Surg. Jour.*, Sept. 29, 1910.

upon the sudden accession of *fever*, particularly if associated with thoracic pain, however slight, following an operation.

Relapses.—These are rare, and are usually rudimentary. *Recurrences*, however, are ordinary (*vide* Predisposing Causes, p. 110).

Course and Duration.—In most instances, the crisis occurs on the seventh or ninth day, and resolution is completed about one week later, making the total duration from twelve days to two or three weeks. Convalescence, however, may be delayed by complications or sequelæ, and fatal cases are apt to terminate on the seventh, eighth, or tenth day.

Termination.—(a) **Delayed Resolution.**—The process of resolution may

FIG. 12.—Lobar pneumonia: 1, unaffected area (upper lobe); 2, consolidated area (middle lobe); 3, resolving area (lower lobe); 4, heart in normal position.

not begin until the fourth, sixth, or even tenth week. Usually defervescence by crisis has taken place long before the physical signs indicate resolution; the fever may, however, fall by lysis. When resolution occurs it may lead to complete restoration of the anatomic entirety of the lung-tissue. Delayed resolution is often confused with certain sequelæ, especially empyema. Rarely proliferation of the interstitial connective tissue arises in postponed resolution, producing (b) **chronic interstitial pneumonia**. (c) **Abscess**; (d) **gangrene**; and (e) **tubercular phthisis** are also sequelæ.

Diagnosis.—The diagnosis is determined by special local and general symptoms, together with the physical signs. Of these, the abrupt onset with rigor, the course of the fever with termination by crisis, the abnormal pulse-respiration ratio, the cough, the rusty expectoration, expiratory “grunt,” and the signs of lobar consolidation, are the most characteristic. Repeated physical examinations of the chest will often

detect consolidation, in the absence of the accustomed symptoms. Again, when in the course of certain chronic affections (cancer, Bright's disease, diabetes, and organic affections of the heart) fever is developed, physical exploration of the thorax is imperatively demanded.

FIG. 13.—Acute pneumonic phthisis, posterior view: 1, cavity; 2 and 3, consolidation; 4, infiltration; the white spots indicate râles.

Differential Diagnosis.—This relates to (a) acute pneumonic phthisis, (b) pneumo-typhoid, (c) meningitis, (d) broncho-pneumonia, (e) acute pleurisy with effusion.

(a) PRIMARY LOBAR PNEUMONIA.

There may have been prior attacks.

Sudden, with severe rigor and rapid rise of temperature.

Fever of continued type, terminating by crisis.

No drenching sweats, except at time of crisis.

Herpes common.

Not much emaciation.

Pulse-respiration ratio considerably disturbed.

Sputum rusty-colored, viscid, and sticky; contains pneumococcus.

Duration of febrile stage shorter.

ACUTE PNEUMONIC PHTHISIS.

Inherited predisposition or previous tuberculous disease.

Generally more gradual—repeated fits of chilliness (rarely severe rigor), often following exposure or "cold."

Fever of remittent type, often becoming intermittent, without crisis.

Drenching sweats present and oft repeated.

Absent.

Rapid emaciation.

Less so.

Sputum may be blood-tinged; is more purulent and copious, and contains numerous bacilli and yellow elastic tissue.

Duration longer.

| (a) PRIMARY LOBAR PNEUMONIA. | ACUTE PNEUMONIC PHTHISIS. |
|--|--|
| Physical signs, as a rule, first referable to base of lung. | First referable to apex. |
| Usually limited to one lobe or the lower segment of one lung. | Usually extension from apex to base. |
| Signs of consolidation, followed by resolution. | Signs of consolidation, followed by cavity-formation, with large gurgling râles at apex. |
| Apex of opposite lung not involved. | Apex of opposite side generally invaded. |
| Prognosis not hopeless. | Hopeless. |
| Tuberculous disease of other organs does not follow as a rule. | Often does. |

(b) *Typhoid pneumonia* must be diagnosed from *pneumo-typhoid*, and the blood in the two conditions may be of service in the discrimination. Leukocytosis usually exists in pneumonia, and there is hypoleukocytosis in typhoid; but this fact is only of value when there is marked increase or decrease of the leukocytes, since figures about normal may occur in either condition. In *pneumo-typhoid*, after the end of the first week, however, undoubted symptoms of typhoid fever arise, and often before this period the Widal test will clear the diagnosis. On the other hand, typhoid pneumonia is characterized especially by great physical prostration, feeble heart-action, and other symptoms of the typhoid state.

(c) *Meningitis* is sometimes mistaken for pneumonia, and particularly when the latter occurs in children. The initial symptom of pneumonia in the very young is often a convulsion; whereas, though in meningitis this symptom is not uncommon, it is more apt to manifest itself later. When headache occurs in pneumonia it is frontal. It is almost invariably complained of in meningitis, but is occipital, and is associated with rigidity of the cervical muscles. Before the occurrence of pressure-symptoms in the latter disease the patient is very restless and morose; his reflexes are exaggerated and there is marked hyperesthesia. The temperature-range is lower, more irregular, and there is no crisis, while the pulse is more variable and often irregular in meningitis. In pneumonia with latent local symptoms the pulse-respiration ratio is greatly altered and the type of respiration peculiar (*vide ante*). The important rule, to examine for the physical signs in doubtful cases, must not be neglected, and if the subject be young the apex region in particular.

The differential diagnosis between pneumonia and broncho-pneumonia and pleurisy with effusion will be found on pages 556 and 590.

Prognosis.—The mortality from pneumonia in hospitals averages about 25 per cent. It is less in private practice—about 15 per cent. The death-rate, however, is greatly modified by the type of the individual epidemic; hence a precise statement as to the percentage of fatal cases cannot be ventured. Wells collected 223,730 cases, which gave a mortality of 18.1 per cent.

The elements that enter into a correct prognosis are in the main identical with those in other acute infectious diseases, and concern (1) the severity of the type of infection, (2) the presence or absence of complications, and (3) circumstances peculiar to the individual.

(1) **Severity of the Type of Infection.**—In sthenic cases this is shown by (a) the temperature-range, (b) the degree of heart-power, (c) the intensity of the nervous symptoms, and to some extent by (d) the size of

the area of lung-induration. It is a matter of common observation that the absence of leukocytosis is indicative of a grave type. In case the diplococcus be found in the blood, the prognosis is by most writers considered grave, but it is to be recollected that with the improved technique of the present day this organism is readily isolated. (a) *The Temperature-range*.—A continued high temperature, as, for example, 105° F. (40.5° C.), on two or three consecutive days without material remissions, is ominous. (b) *The Degree of Heart-power*.—A steadily rising pulse-rate after the fifth day indicates real danger, since it points indisputably to gradual cardiac failure. The same thing is shown by a diminution in the intensity of the second pulmonary sound; it indicates the giving out of the right ventricle. (c) *The Intensity of the Nervous Symptoms*.—Active delirium is not favorable at any stage, and is particularly unfavorable if it develop early. When it assumes the form of delirium tremens the case has usually passed beyond the hope of recovery. (d) *The Size of the Area of Lung-induration*.—I have observed that extension of the consolidation at an advanced stage belongs to serious types. The same may be said of double basic pneumonias.

Typhoid pneumonia, being of low type, gives an unfavorable prognosis, notwithstanding an absence of high temperature and of extensive inflammation of the lung-texture.

(2) **Presence or Absence of Complications**.—Cases in which there is involvement of a single lobe or two lobes, if it occur on the right side and without complications, generally terminate in recovery. In nearly one-half of the instances complications occur, and these greatly increase the death-rate. Among the most common is *pleurisy*, which, unless accompanied by considerable effusion, does not add fresh danger; when pleurisy attacks the non-affected side, however, it does. *Empyema*, following pneumonia, generally terminates in recovery unless septic phenomena are superadded. Extensive *bronchitis* is a most perilous complication in my judgment. *Pericarditis* decreases the chances for recovery, but by no means to the same extent as ulcerative *endocarditis*. *Cardiac clots* may form, but usually the patient is already moribund. *Abscess of the lung* and *gangrene* form highly unfavorable complications. *Congestion* and *edema* of the uninvaded portions of the lungs render the outlook bad, and these, together with cyanosis, are apt to be dependent upon failure of the right heart. *Acute meningitis* is exceedingly grave. Fenwick, as the result of an analysis of 10,000 cases, found that the quantity of albumin in the urine is of considerable prognostic value. *Gastro-intestinal* complications occurring at the outset are unpropitious.

(3) **Circumstances Connected with the Individual**.—Of these *age* heads the list, and after the twentieth year the mortality increases progressively until the seventh decade, when it rises more abruptly. It has been claimed that nine-tenths of the deaths after the seventy-fifth year are from lobar pneumonia. Under the twentieth year, according to the analysis of 708 cases at St. Thomas's Hospital by Hadden, H. W. G. Mackenzie, and W. W. Ord, the mortality is 3.7 per cent.

Sex has little influence. Napier's figures indicate that pneumonia is a more deadly disease in men than in women. The *alcoholic* rarely escapes death, and *adiposity* is an unfavorable condition.

Modes of Death.—Death is due to: (1) overwork or overdistention of the right ventricle; (2) from mechanical interference with respiration (rare); (3) pneumococcus infection of other organs, as the meninges, pleura, pericardium, endocardium; (4) pneumococcus toxemia as shown by the typhoid state, *progressive heart weakness*, tympanites, and diarrhea; (5) vasomotor paresis is often the cause of death.

Treatment.—**General Management.**—The patient should be isolated in a well-aired apartment. Fresh air constantly breathed improves the appetite, lessens cough, diminishes the temperature, pulse-rate, and respiration-rate; in short, a less marked toxemia is observed than in patients treated by the more usual method.¹ Spolverini² points out that the pneumococcus in the sputum may remain virulent from fifty-five to one hundred and forty days, hence it is important to sterilize pneumonic sputum. An antiseptic mouth-wash should be advised. In severe forms the constant presence of a physician is required. The patient must be kept at *perfect rest*, and not allowed to leave his bed for at least one week after the occurrence of the crisis. The beneficial effects of rest, in the fullest sense of the term, are not appreciated to the extent they deserve. Perhaps the principal object is to support the powers of life until the crisis is passed.

The diet should be light, chiefly liquid, but of the most nutritious sort. *Milk* should constitute the chief article of diet; meat-broths or meat-juices, egg-white, and light farinaceous substances may also be allowed. The food, particularly the milk, is to be administered at stated brief intervals and in definite quantities. When resolution is delayed stronger forms of nourishment (scraped meat, etc.) may be given. After the crisis a gradual return may be made to the usual forms of solid foods. Page³ and others advocate abstinence from practically all nourishment *except water*. Alcohol has considerable food-value; it lessens waste and improves the appetite and digestion. To accomplish this object, it should be given in small amounts, two or three ounces daily.

The *medicinal treatment* is that of a *toxemia*, although the patient himself is the main factor.

The use of calomel in fractional doses or one of the saline laxatives in the early stage is an important procedure. Subsequently the liver and bowels must be kept acting freely, so as to eliminate waste products and toxins, and to obviate "absorption of fermentative products from the alimentary canal" (Thornton). The action of the kidneys is best maintained by the regular use of water and that of the skin by sponge-baths. Stockton advises stimulation of the eliminative organs—skin, liver, kidneys—in senile pneumonia.

Cardiac stimulants are often indicated. It is well to begin their use as soon as the slightest tendency to cardiac failure is shown. When the pulse becomes more accelerated and feeble, the first sound of the heart less distinct, and the second pulmonic sound loses its accentuated character, or marked nervous symptoms or adynamia appear, then alcoholics must be used. At first they are to be employed in moderate doses ($\frac{1}{2}$ ounce—16.0—of whisky or brandy every three hours), to be increased

¹ *Medical Record*, 1906, No. i, p. i, by the writer.

² *Centrab. f. allg. Path. u. pathol. Anat.*, July 18, 1900.

³ *Medical Record*, Dec. 23, 1905.

if the effect be favorable proportionate to the urgency of the indication. In the pneumonia of drunkards its early use is to be recommended.

If the alcoholic stimulants fail, other cardiants must be administered simultaneously. Of these, strychnin has been the most serviceable in my own hands, its mode of administration following the same rules as have been mentioned for alcohol—at first in moderate-sized doses, to be increased as occasion demands. Should urgent need of stimulation arise, strychnin should be exhibited hypodermically. It is my custom in desperate cases to use subcutaneously as much as gr. $\frac{1}{15}$ (0.0043) every two or three hours. As soon as the condition of the heart denotes restoration of cardiac power the size of the dose is to be reduced. In no other disease do strychnin and alcohol possess greater potency for good than in pneumonia; they lessen the depressing effect of the poison. For sudden heart-failure ether, administered hypodermically, is also very efficacious. In severe forms of pneumonia digitalis is invaluable during the advanced stages; it may be given in doses ranging from 5 to 15 minims (0.333–0.666) of the tincture every third hour. In cases in which extreme cardiac weakness with depression of respiratory forces supervenes the drug is to be administered hypodermically in the same dosage. Strychnin may be combined with the digitalis. The effect upon the pulse and heart-sounds should be the criterion of sufficiency. S. West¹ sees most benefit from caffein citrate with nux vomica. Recent experience enables me to speak strongly in favor of atropin administered subcutaneously in the threatened collapse that sometimes attends the crisis. Nitroglycerin is especially indicated when the renal secretion is scanty and the urine contains more than the usual trace of albumin. Ammonium, adrenalin chlorid, and camphor (gr. 1 to 2—0.027–0.054) in sterile oil, hypodermatically, are also excellent stimulants to the feeble heart of pneumonia.

Peripheral stimulants, such as cold or heat, either locally or generally, may be useful after the blood-pressure falls; they should be combined with the use of the saline injections with a view to filling the blood-vessels. It is claimed by some that central stimulation to an over-acting heart may hasten exhaustion rather than prevent the same.

Saline injections, given either intravenously or subcutaneously, are valuable in overcoming a falling blood-pressure with increasing toxemia. The hypodermic method is preferable. From 1 to 2 pints (strength 0.7) may be injected, and allowed to flow under the skin from a rubber bag; and this may be repeated at intervals of eight hours if necessary. For an acute exacerbation of a chronic nephritis in the course of pneumonia, venesection with saline infusion is worthy of careful trial.

Respiratory Stimulants.—Beginning cyanosis is the signal for the use of respiratory stimulants, of which the best are strychnin and atropin, and they should be given hypodermically. *Oxygen*, if given freely, often serves to tide over periods of marked cyanosis. The gas should be inhaled directly from the cylinder until relief is afforded, when it may be allowed to escape near the patient's nose, so as to become mixed with air. Stoker² advises the continuous use of oxygen from the moment the disease declares itself.

¹ *British Medical Journal*, March 11, 1908.

² *Medical Press and Circular*, 1908, lxxxvi., 90.

Hydrotherapy.—In meeting high temperature, marked nervous symptoms, dyspnea, cardiac weakness, etc., hydrotherapy offers many superior advantages. When the temperature is high, ice-bags over the chest and abdomen are useful. Tub-baths have been for the most part omitted from consideration in the treatment of lobar pneumonia, rest being of the greatest importance. Cool sponging, combined with the ice-cap or the wet pack, serve as a substitute for the full baths (*vide* Local Measures *infra*).

Abortive Method of Treatment.—Petresco found large doses of digitalis (3j-ij—8.0 of the digitalis leaves in an infusion daily) administered at the onset to jugulate the disease. His experience covered 1192 cases, and showed a mortality range of 1.22 to 2.66 per cent. This plan of treatment is rational, since it aims at meeting the chief pathogenic indication of pneumonia by passing through the lung-tissue an adequate proportion of leukocytes, and thus re-establishing the cardiopulmonary circulation.

Venesection.—This is a good measure in sthenic cases (which are not uncommon in rural districts), the temperature falling, the pain, the dyspnea, and the nervous symptoms being relieved and the pulse softened. The bleeding, however, must be free and rapid. Later in the course of pneumonia venesection may be resorted to if cyanosis and the signs of collateral pulmonary edema—due to a failing heart—arise, but at this period bleedings rarely yield good results, except in vigorous subjects.

Antiseptic Method.—This method is based upon etiologic indications, and is most rational. The best antiseptics are carbolic acid (mj—0.066, every four hours), thymol (gr. ij-ijj—0.129–0.194, every four hours), mercuric chlorid (gr. $\frac{1}{100}$ —0.0006, every four hours). Creasote carbonate has been warmly advocated by Wilcox and others, and it merits a careful trial. It is claimed that this remedy aborts a large percentage of cases and mitigates almost all the rest; it tends to nullify bacterial activity, thus inducing crisis. Citric acid, given to diminish the coagulability of the blood, has proven to be a valuable remedy.

Antipneumococcus Serum and Serum obtained from Convalescents.
—Washbourn, Pane, Fanoni, and others have reported favorable results from the use of antipneumococcus serum. On the other hand, many clinicians who have employed the serum are skeptical as to its therapeutic efficiency. It seems to possess considerable protective power, as shown by the Klemperer brothers (*vide* p. 110). I have collected 535 cases treated by serum therapy—61 cases by diphtheritic and 474 by antipneumococcic serum—with 85 deaths, a mortality of 18.3 per cent.¹ The results obtained by different observers are variable and fail to carry conviction. The use of killed cultivations, or “vaccines,” are found to be useful (Latham and others). The estimation of the opsonic index is unnecessary.

Treatment of Special Symptoms.—The initial pain, when it is of an acute, agonizing character, is relieved by the hypodermic use of morphin. This counteracts the shock produced by the invasion-period, but it is to be omitted if the bronchi contain secretory products, since morphin dries these and favors their accumulation rather than their removal. Rarely is it necessary to continue this remedy after the second day.

Fever.—The fever of pneumonia is a temporary affair, and instead of being hurtful may prove beneficial, since it furthers tissue-metabolism, and this aids in the destruction of the specific poison of the dis-

¹ *Jour. Amer. Med. Assoc.*, Dec. 10, 1904, p. 1777.

ease. Fortunately, internal antipyretics for the purpose of combating high temperature are not so largely used at the present day as formerly. It is true they possess the power to reduce temperature, but their use is attended with danger from their action as cardiac depressants; while, if it be true, as before stated, that pneumonia usually kills through the heart, it follows that cardiac power must primarily be conserved. I have abandoned their use. (See Hydrotherapy, p. 128.)

In cases in which venesection is indicated the tinctures of veratrum viride and of aconite have been much vaunted as substitutes. The tincture of veratrum viride produces a good effect upon the congestion in the early stage, since it relaxes the arterial walls, and thus bleeds the patient into his own vessels, and "allows the return of the blood to the circulation when the stage of consolidation is reached" (H. C. Wood). It should be discontinued after the second day of the illness. The tincture of aconite, owing to its depressing influence upon the heart, should not be employed. The alkalies (*e. g.*, sodium carbonate) are employed, to neutralize the acid produced by the causative bacteria. The salts of the organic acids will serve the same purpose (Brown) as potassium citrate.

The nervous symptoms are successfully met, as a rule, by hydrotherapy (including the ice-cap), by the arterial stimulants, and by the use of morphin, as before recommended.

Cough during the early stage is controlled by the morphin needed to combat the pain. In the more advanced stages, if there be present numerous moist râles and a scanty expectoration, stimulant expectorants (ammonium muriate, terebene) may be employed with happy effect; but ordinarily they do harm rather than good. Pilocarpin may aid resolution when this is delayed (Reiss); the heart must be guarded.

Complications.—The management of the complications does not differ from that which is appropriate when they occur as independent affections, though all depressing measures must be positively omitted. I would add that in pleuro-pneumonia aspiration is not well borne. Suppurative arthritis should be treated by incision and drainage.

Among measures to prevent *ether-pneumonia*, and in all cases of lobar pneumonia, I would urge an appropriate toilet (a thorough cleansing followed by the topical use of an efficient antiseptic solution) of the nasopharynx and mouth as a routine practice. Pneumonia occurring in malarial subjects demands the use of quinin.

Local Measures.—When in doubt as to whether venesection should be employed or not, it must be remembered that early local bloodletting (cupping, leeching) is followed by relief from pain and dyspnea, but that these measures should be reserved only for robust persons. Counter-irritation by means of sinapisms is useful at the onset, and if pains be severe, strapping the side affected gives much comfort. The cotton jacket has certain advantages in maintaining the free, local action of the skin. The *topical use of cold* in the form of ice-bags has been practised extensively by Lees of England and Mays of America with brilliant success. Other hydiatic measures, suggested by Baruch, as cold compresses, wrung out of water at a temperature of 60° F. (15.5° C.), and applied to the anterior and posterior portions of the chest (the edges overlapping in the axilla), give similarly good results. They should be made of several thicknesses of muslin, held together by basting, covered by flannel, and firmly secured by safety-pins. A reapplication every half hour or hour is advised.

SECONDARY PNEUMONIA.

Pathology.—The lesions are identical in character with those of primary lobar pneumonia, but the areas involved have not always the same regular distribution. Congestion surrounding the hepatized lung-tissue is not infrequently extensive. We see, post-mortem, a tendency to commingling with small areas of lobular pneumonia. Both the streptococcus and the micrococcus lanceolatus are frequently found on microscopic examination.

Etiology.—Most instances are secondary to the acute infectious diseases, and it is probable that the specific causes of certain of the latter (Eberth's bacillus, Pfeiffer's bacillus, etc.) have the power to excite the morbid changes of acute lobar pneumonia. *Colon-pneumonia*, due to the bacillus coli, is the result of hematogenous infection either from the intestinal or from the urogenital tract. In the majority of instances, however, in which this disease develops in the course of the acute infectious diseases the latter are to be regarded as merely furnishing the opportunity for infection by the micrococcus lanceolatus.

Symptoms.—The rational symptoms are often absent. Close observation may, however, detect more or less dyspnea, cough, and increased fever, and rarely the attack is heralded by a rigor, followed by fever, the pneumonic type of breathing, pain, cough, and the characteristic expectoration.

The physical signs, when carefully observed, usually serve to enlighten the physician as to the nature of the affection. Hence it is a natural corollary that repeated physical examination is demanded in all cases in which there is danger of intervening lobar pneumonia.

Diagnosis.—This rests chiefly upon the physical signs, which are the same as in primary lobar pneumonia. Obviously, when the local subjective symptoms and the characteristic sputa are present a correct diagnosis is easily made. The fact must be emphasized that bronchopneumonia arises in the course of infectious diseases far more frequently than does lobar pneumonia.

Prognosis.—The occurrence of lobar pneumonia as an intercurrent affection adds greatly to the gravity of the primary disease. It is especially dangerous when it appears as a sequel during convalescence from acute infectious diseases.

The treatment is similar to that of primary lobar pneumonia, though less satisfactory.

INFLUENZA.

(*La Grippe: Epidemic Catarrhal Fever.*)

Definition.—Influenza is an acute contagious disease, probably caused by the bacillus of Pfeiffer. Its chief symptoms are due to catarrh of the respiratory and digestive tracts, together with profound muscular and nervous prostration, and grave complications (especially pneumonia) often present themselves. The disease may be endemic, though oftener it prevails in an epidemic or pandemic form.

Historic Note.—Every quarter of the globe has been the scene of visitations of epidemic influenza. More rapidly than any other disease belonging to the same class does it traverse a region of country. As a rule, influenza develops into epidemic proportions in the East, whence it spreads with unparalleled rapidity in a westerly direction. The first epidemic of the disease in the United States appeared in 1647, and was subsequently described; and, though it has since then frequently prevailed, the outbreaks have not observed any regular periodicity. The last true pandemic of the affection originated in Bokhara in May, 1889, reached St. Petersburg in the following October, Paris in November, and London in turn early in December. In America the cases began to appear about the middle of December, and rapidly multiplied into an explosive epidemic, which reached its maximum in January, 1890. Influenza reappeared in epidemic form, though less extensively, during April and a part of May, 1891, and again in a briefer and lighter form in the winter of 1891–92. During the winter of 1892–93 only a few sporadic cases occurred. Subsequently, it prevailed in an epidemic form annually for seven successive years in limited sections of this country. During the early part of 1901, and again in the winter of 1902–03, pandemic visitations of the disease occurred in the United States.

Pathology.—There are no special anatomic lesions that characterize the disease. In the rare instances in which death occurs in uncomplicated cases the catarrhal changes of the respiratory and gastrointestinal mucosa disappear after death. In the abdominal type of the affection there may be enlargement of the glands of Peyer and of the solitary follicles. Among the fatal complications are pneumonia (either lobular or lobar), serofibrinous pleurisy, empyema, purulent pericarditis, nephritis, and rarely cerebrospinal meningitis and acute hemorrhagic encephalitis. All of these, however, may rarely be of influenzal origin.

Etiology.—**Bacteriology.**—Early in the year 1892 Pfeiffer discovered the *influenza bacillus*. It is of about the same breadth as the bacillus of mouth-septicemia, and only one-half the length of the latter. When stained by the aid of gentle heat with Ziehl's carbol-fuchsin, one part; water, nine parts, or Loeffler's methylene-blue, it may be observed as a small dumb-bell, having knobbed ends connected by a rod-like shaft. These bacilli are obtained from the sputum and nasal secretions. Pfeiffer has shown that they may penetrate the peribronchial tissue and pass out to the pleura. They have also been found in the blood and other tissues. This bacillus can be cultivated only in media containing hemoglobin, and when inoculated into rabbits it causes symptoms resembling those of influenza. While the bacillus of Pfeiffer is generally supposed to be the sole pathogenic agent, this has not as yet been proved. The organism probably causes an intoxication and not an infection. Influenza is a common *secondary infection*, especially in childhood, and may occur in measles, diphtheria, scarlet fever, and other infections.

Modes of Conveyance.—A specific germ that is propagated with the unusual rapidity that marks the bacillus of Pfeiffer must be air-borne.

Pepper suggests that the micro-organism may be almost universally distributed, and that under certain extraordinary atmospheric or telluric conditions it acquires a degree of virulence that renders all subject to its attack. Influenza is communicable by *contagion*, and evidence is abundant to show that it may be transferred by *fomites*. In some epidemics the disease travels slowly, and follows principally the lines of ordinary human and commercial intercourse.

Manner of Invasion.—The contagion probably enters the system with the inspired air through the respiratory tract. Some contend that the infection atrium is the alimentary canal, while others believe that the primary point of infection may be the conjunctiva.

Predisposing Causes.—All persons are liable to the contagion. *Age* has slight influence, the period of greatest susceptibility being from the twentieth to the thirtieth year. The very young are least susceptible, and during an epidemic are apt to be affected last, while old persons are frequent sufferers. Subjects whose vitality is lowered by neuropathic heredity or chronic maladies are among the first to suffer during an epidemic.

Immunity.—A primary attack of influenza does not bestow immunity, since *relapses* are very common, in 10 per cent. of the cases (Turney). Many persons, too, suffer from the disease with the reappearance of fresh epidemics, so that two, three, four, or even more attacks may be observed in the same individual (*recurrences*). Recent investigations have shown that a decided antagonism exists between influenza and malaria.¹ Epidemic influenza increases susceptibility to pneumonia and probably also to typhoid fever and appendicitis.

Clinical History.—**General Symptomatology and Course.**—The *incubation period* is quite brief, rarely exceeding two or three days. The *onset* is generally sudden, with either a severe rigor or repeated slight shiverings, accompanied by a rapid elevation of temperature which may touch 104° or 105° F. (40.5° C.), intense headache, distressing myalgic pains, and great prostration. The primary fever, however, varies greatly in severity, as does also the character of the symptoms—both local and general. Profound prostration characterizes the vast majority of instances during the invasion period. Depression of spirits, restlessness, insomnia (more rarely undue somnolence), and frequently delirium are among the prominent nervous phenomena.

Rare Modes of Invasion.—The infection may set in (*a*) by vertigo, (*b*) by apoplectic features, (*c*) by bilious vomiting, (*d*) by an abrupt and profound prostration. Nose-bleed sometimes occurs.

The most striking symptom is *pain*, which in many cases is referable chiefly to the forehead, temples, occiput, eyeballs, and root of the nose. General neuro-muscular pains are often present. The principal seat of the pain is commonly the lumbar spine (rachialgia). I have frequently noted cutaneous hyperesthesia. The pains may take the form of neuralgia of individual nerves or of pleurodynic stitches, or there are

¹ "A Statistical Study of Influenza; its Potency to Lessen the Receptivity of the Body for Malaria, as well as to Increase the Receptivity for Pneumonia and, probably, Typhoid Fever," by the writer.—*Philadelphia Hospital Report*, 1895, vol. iv.

localized areas of burning, boring muscular pain. The *temperature* may, as before intimated, mount quite high at the beginning, and if so it usually remits during the first night. It subsequently pursues a comparatively low range. The temperature-curve is markedly irregular, and often terminates by an apparent crisis. The *pulse* is small, feeble, running, irregular, and even intermittent, and I have sometimes observed it to be unusually slow. The depressing effects of the poison upon the heart often reach a dangerous degree. No leukocytosis is present as a rule. An occasional mild leukocytosis (10,000–15,000), however, is noted in uncomplicated cases. In many cases *dyspnea* is a rather conspicuous symptom, occurring independently of pulmonary complications. The same is true of *cyanosis*. Sweating may be troublesome.

Clinical Types.—Different types have been described based on the differences in the local manifestations and the varying degrees of toxemia. Influenza is remarkably protean in its features, and the enumerated types quickly and frequently merge into one another. (a) *Respiratory Type*.—Local catarrhal symptoms usually develop in the course of one or two days. They are, as a rule, evidenced first by a suffusion of the conjunctivæ, with excessive lacrymation, frequent sneezing, and slight pharyngitis. A little later, in most instances, hoarseness and cough come on, the latter being hard, racking, paroxysmal in character, and resembling whooping-cough. The cough and other local symptoms are due to an intense, dry laryngo-tracheal irritation. In most instances the expectoration is scanty, and in these the physical signs are very generally negative. In a smaller proportion of the cases there is considerable expectoration, and the physical signs of ordinary bronchitis are manifested. (b) *Gastro-intestinal Type*.—The catarrhal symptoms may center in the digestive system, most frequently in children. In such, vomiting comes on early and is apt to be repeated at longer or shorter intervals. There is diarrhœa, more or less urgent, with sharp abdominal pain, as a rule. (c) The *cardiac* group of symptoms that occasionally supervenes comprises heart-failure and distress, with a rapid, feeble pulse (a toxic form). (e) The *nervous* or *typhoid* (toxic) *type* presents a continued fever, with the signs of the typhoid state. Two classes of nervous symptoms are seen—"comatose and delirious" (Bury). Patients may be seized with intense headache, or an epileptic or apoplectic fit, or there may be local paralysis or hemiplegia. Muscular rigidity, especially of the neck, is far from uncommon. (e) The *rheumatoid type* manifests itself by violent pains in the muscles all over the body. There is no visible change in either the joints or the nerve-trunks. (f) Huchard¹ calls attention to *apyretic forms*, in which there may be marked pulmonary congestion or actual lobar pneumonia without fever, without expectoration, and often without cough. (g) There are ambulatory forms which are important because they tend to spread the affection. (h) Franke describes a chronic form assuming the guise of catarrhal affections of the respiratory and gastro-intestinal passages. The raspberry tongue is characteristic of chronic influenza.

Leading Features and Complications.—(1) **Pulmonary.**—Severe bronchitis, particularly affecting the capillary tubes and leading to bronchopneumonia, is a common and very serious complication. As a

¹ Bull. Acad. de Méd., Feb. 17, 1900.

secondary result we are apt to observe the development of collateral pulmonary edema, with its usual fatal termination; and while this complication is prone to develop in the so-called thoracic type of influenza, it is by no means limited to this class of cases. I have observed bronchopneumonia in cases in which the physical signs of bronchitis were not presented prior to its onset. It may originate apparently in the profound prostration of the nervous system—a condition which also annuls in great part the phagocytic action of the leukocytes. As a rule, both broncho- and croupous pneumonia may be definitely traced to exposure.

The nature of the condition is variable, and may at times be ascribed to *congestive collapse* and other conditions, rather than to the ordinary type of bronchopneumonia. *Congestion associated with edema* of the lungs occurs as a complication of influenza. Enlargement of the bronchial glands may also be noted, and the recognition of this condition may be aided by careful percussion over the upper four dorsal vertebræ, where dulness will be obtained (*vide* Streptococcus-pneumonia, p. 120).

Lobar pneumonia is also a frequent and very fatal complication. It may arise early and in rare instances insidiously, but it is much more apt to manifest itself after influenza has about exhausted its force upon the vital organs or during the early part of convalescence. The symptoms of invasion—severe chill, high temperature, followed by the usual physical signs—are *sudden in their onset* and lead rapidly to an extremely serious condition.

When lobar pneumonia develops early in the course of influenza (a rare event), its symptoms are modified, the preliminary chill and pain in the side being often absent, and more frequently still the characteristic crepitant râle. Subcrepitant râles, however, are audible, and the dyspnea is out of proportion to the area of lung-tissue involved. Most of these features may also be observed in connection with the pneumonia that appears during convalescence. Marked leukocytosis is present as a rule. (See Apyretic Varieties, p. 133.)

Plastic pleurisy is commonly an associated condition, especially in cases of lobular or lobar pneumonia. Other forms of pleurisy also occur, though less frequently (sero-fibrinous and empyema). *Gangrene* and *abscess* of the lungs may arise as terminal complications.

Cardiac Complications.—Heart-failure often manifests itself, and may prove fatal, though rarely. Purulent pericarditis is a rare complication, and is often secondary to pleurisy or pneumonia, while attacks of angina, which usually interchange with simple weak heart (often associated with arrhythmia), have been noted in certain epidemics (Curtin and Watson).

Gastro-intestinal System.—There may be severe gastro-enteritis (particularly in children), with frequent vomiting and purging and abdominal pains, and, more rarely, hemorrhages occur from the stomach and bowel (*vide Gastro-intestinal Type*). Catarrhal jaundice may appear. Appendicular inflammation may be induced by influenza. These, and all other complications may be due to the influenza bacillus.

Nervous System.—The most frequent symptom is perineuritis, which probably causes much of the patient's sufferings. A soporose or even comatose condition may be observed. Delirium of a most active form sometimes appears, and particularly when certain other complications

have arisen (pneumonia, pericarditis). Cerebro-spinal meningitis occasionally occurs. I have observed symptoms identical with those of meningitis appearing suddenly, and in the course of a day or two disappearing just as suddenly. In addition to these symptoms, we should have the existence of suppuration elsewhere in the body (otitis, purulent pericarditis) or of pneumonia. A positive diagnosis demands the finding of the specific organism by means of lumbar puncture. Cerebral abscesses have also been noted (Bristowe). Kerr has reported disseminated lesions of the central nervous system following influenza. The severer nervous features and complications are mostly observed in the typhoid type of the disease.

Genito-urinary Tract.—Renal congestion, and even acute nephritis, may appear as a complication. A case of cystitis with hematuria has also been reported (Comby and Le Gendre).

The **diagnosis** of influenza except in ill-defined, sporadic cases rarely presents difficulty. Usually, the march of the epidemic, the abrupt onset, with alternating flashes of heat and chilliness, the brevity of the febrile stage, headache, sore eye-balls, rachialgia, and a prostration out of proportion to the catarrhal manifestations, form a conclusive assemblage of symptoms. In all cases, more particularly the obscure forms, the sputa, if there be any, should be studied microscopically. The bacillus of Pfeiffer may be conveniently stained with a solution of fuchsin-rubin (gr. 0.01 in 100.0 aqua destillata). Franke invites attention to the band-like redness of the half-arches as a diagnostic criterion.

(a) *Climatic catarrhal affections* are sometimes hard to discriminate from sporadic cases of influenza. The former are usually attributed to sudden and great vicissitudes of temperature or exposure to strong drafts of air, while the latter come on independently of such agencies. Again, in influenza the general features (nervous symptoms and debility) outweigh the local (catarrhal manifestations). Leichtenstern speaks of pseudo-influenza, or catarrhal fever (*influenza nostras*), believing that it bears the same relation to true influenza as does cholera nostras to Asiatic cholera. Its cause is unknown.

(b) *Typhoid fever*, particularly in its early stages, is often closely simulated by influenza with intestinal symptoms. Influenza, however, gives the history of the prevalence of an epidemic, begins suddenly, does not show the typical temperature-curve of typhoid, may present splenic enlargement—but by no means to the same extent as typhoid—has no characteristic eruption, and does not give the characteristic sero-reaction. Again, the Pfeiffer bacillus may be discovered in the nasal and bronchial secretions in influenza.

(c) *Pneumonia* has quite frequently been mistaken for influenza, and especially when the thoracic symptoms in the latter have been unusually distinct. As already stated, lobar pneumonia may early complicate influenza in rare instances; but pneumonia is generally unilateral, while the lung-involvement in influenza is generally bilateral. In the former the physical signs indicative of consolidation are present; in the latter (unassociated with pneumonia) those suggestive of congestive edema (impaired resonance, stationary subcrepitant râles). The general features also present dissimilarities. Thus the nervous depression and the myalgic and neuralgic pains are more marked in influenza, while the pulse-respiration ratio is less disturbed than in pneumonia.

(d) *Cerebro-spinal meningitis* may manifest features that are almost identical with those characteristic of influenza. Thus during certain epidemics "grippe" patients may be stricken as by a blow; they suffer from intense headache—occipital and frontal—rachialgia, fever prostration, delirium, and stiffness of the muscles, with slight retraction of the head. There may be convulsions and vomiting at the outset. Here the history with reference to the character of the prevailing epidemic and the attendant circumstances must be carefully considered, but an absolute diagnosis is sometimes impossible unless a laboratory investigation of the discharges or lumbar puncture be made.

(e) Small-pox, in the pre-emptive stage, may be confounded with influenza, but the latter is soon diagnosticated by quick response to therapy and sweating, relieving the symptoms in twenty-four to thirty-six hours, whereas small-pox is resistant to all treatment, the appearance of the rash only bringing amelioration of the symptoms.

Sequelæ.—Among the sequelæ are phthisis, chronic bronchitis, abscess and gangrene of the lungs (the latter two being rare), tachycardia, and angina pectoris. Chronic gastro-intestinal catarrh, chronic nephritis, and less frequently cystitis, may also be mentioned. Latent forms of tuberculosis and chronic nephritis are often kindled into active and progressive affections by intercurrent influenza.

Among *nervous* sequelæ, which are both numerous and important, are to be noted especially insomnia, neuralgia, migraine, melancholia, with tendency to self-murder, meningitis, acute ascending myelitis, peripheral neuritis, and perineuritis. The organs of special sense manifest a great variety of sequelæ, such as otitis media, otitis interna, mastoid abscess, conjunctivitis, keratitis, iritis, irido-choroiditis, acute glaucoma, etc.

Prognosis.—The prognosis is, on the whole, good. Almost all fatalities are due to complications, especially *pneumonia*, and, less frequently, pulmonary congestion and edema, pleurisy, pericarditis, and cerebro-spinal meningitis. The comatose type is often fatal.

The *circumstances connected with the individual case* often affect the outcome. Thus influenza runs a more severe course, and hence offers a correspondingly more serious prognosis, in those enfeebled on account of previous chronic disease (phthisis, valvular disease of the heart, emphysema, nephritis) and in the young and the old than at other periods of life. During severe epidemics of influenza the mortality-list in most chronic diseases is considerably augmented. Though epidemics vary as regards the mortality, the general average death-rate is a little under 1 per cent. In some epidemics it may reach 2 per cent., while in others it may be less than $\frac{1}{2}$ of 1 per cent.

Duration.—The *duration* of the attack is brief, though subject to variations. In mild forms it is from two to four days, in the severe from seven to ten days; but complications and previous infirmities may prolong the attack. The *duration of particular epidemics* rarely exceeds from four to six weeks. Convalescence is usually protracted.

Treatment.—**Prophylaxis.**—Drugs which have been counselled for their preventive effect (quinin, salicin) are devoid of value. Those who are at either extreme of life or who are enfeebled by chronic organic disease, should be most carefully protected by proper wearing apparel, and should not be carelessly exposed to unfavorable weather conditions.

The inmates of hospitals and prisons have been known to escape the disease. Isolation should, therefore, be carried out in hospitals, and, whenever practicable, in private families, especially when the disease appears in households in which there are young children and aged persons. E. W. White has reported an epidemic of influenza that was successfully aborted by strict isolation of the patients. Disinfection of the catarrhal discharges, particularly the bronchial, which, as a rule, abound in the bacilli of Pfeiffer, is necessary. I must also insist upon disinfection of the naso-pharynx and mouth cavity.

Treatment of the Attack.—The cases may be grouped under three heads:

(a) **Mild or Rudimentary Form.**—The cases belonging to this type require careful hygienic management. However light the attack, the patient should remain in-doors and, if prostrated, in bed for a period of two or three days. The *diet* should be light and nutritious (milk, eggs, rice, gruels, fresh vegetables, stewed fruit), and cooling drinks are to be preferred to hot ones, among the former lemonade or cold oatmeal-water with lemon, and effervescent mineral waters (Apollinaris, lithia, Seltzer), being the best. The bowels should be moved regularly, avoiding, however, active purgation. The use of light wines is not objectionable if desired by the patient. In all cases of influenza, even of the mildest grade, I prescribe moderate doses of quinin (gr. iv—0.2592, three or four times daily), and if there be much headache combined with it, Dover's powder and monobromate of camphor (of the first two, gr. iiij—0.194, each, and of the last gr. j—0.0648, in capsule), the dose to be repeated at intervals of three or four hours. To overcome the languor and debility I have found nothing so successful as strychnin.

(b) **Cases of Medium Severity.**—*General Management.*—This class of influenza patients betake themselves to bed, and should be kept there till convalescence is well advanced. During the febrile period the *diet* must be light, liquid, yet nutritious, and the food should be given every two or three hours. Although the patient has no desire for food, he should be urged to take it regularly. Moderate stimulation is also useful.

The *medicinal treatment* is, for the most part, simple and symptomatic. Calomel in moderate doses (gr. j every third or fourth hour) should be a remedy of choice for a day at least. An efficient diaphoretic, given within six or eight hours from the time of onset, may abort the attack. The neuralgia and myalgia may be relieved by the use of quinin, Dover's powder, and ergot; but if the pain be intense, morphin administered subcutaneously may be required. The temperature is somewhat reduced by these remedies, and especially by the quinin and Dover's powder, the latter acting as a diaphoretic. In addition, I am in the habit of ordering cool sponge-baths at intervals of two or three hours if the temperature be about 102° F. (38.8° C.). If not controlled in this manner, we may combine with quinin some antiseptic, such as salicylic acid or salol. I have sometimes found it necessary to add to the foregoing small doses of phenacetin (gr. ij—0.129). *Sleeplessness* may demand hypnotics, such as sulfonal, chloralamid, opium, and trional. It is necessary to utter a warning against the free use of coal-tar products, since they induce heart-failure.

The local catarrhal conditions (coryza, laryngo-bronchial irritation,

true bronchitis, etc.) must be treated according to the special indications presented in individual cases. For the coryza inunctions of animal fats over the forehead and bridge of the nose are useful. A flannel cap may be worn if agreeable to the patient. Steam inhalations through the nares and mouth often act beneficially, both upon the coryza and laryngo-bronchial irritation. For the latter common condition the following formula will be found serviceable:

| | |
|---------------------|---------------------------|
| R. Codeinæ sulph., | gr. iv (0.259); |
| Ammon. chloridi, | ʒv (20.0); |
| Syr. prun. virgin., | fʒij (60.0); |
| Spts. junip. comp., | q. s. ad fʒiv (120.0).—M. |

Sig. One teaspoonful every two or three hours.

If this prescription fail to mitigate the cough, we may resort to morphin hypodermically, but always in small doses. The bronchitis may sometimes be controlled by the use of sodium benzoate, ʒij (gm. viij) in aq. menth. pip., ʒiv (gm. 120) of which a tablespoonful may be taken every two or three hours. In the later stages, particularly if bronchitis be associated with free secretions, the oil of eucalyptus (ʒiij to v—0.199 to 0.333), in capsule, every four hours, has in my experience proved useful. To obviate pulmonary complications I have been much gratified with the results from the use of strychnin (gr. $\frac{1}{30}$ —0.0021), combined with the extract of gentian (gr. j—0.063). Chest-pains may be relieved by the use of turpentine stupes and sinapisms.

(c) **Severe Forms.**—The *general management* is similar to that recommended in cases of medium severity, excepting that freer stimulation is usually demanded. The medicinal treatment must also be more active than in the previous form, and often is heroic. Especially must quinin be given and continued, since it not only serves to reduce the temperature somewhat, but also to sustain the vital forces, to control the nervous symptoms, and lessen the tendency to inflammatory complications. Depressants are to be avoided. Should there be sudden cardiac failure, it must be promptly met by cardiac stimulants (strychnin, camphor, ether, digitalis) given hypodermically. In addition to alcoholic stimulants, the aromatic spirits of ammonia is usually borne well, and should be administered. The various inflammatory complications must be treated as under other circumstances.

The Convalescence.—The greatest injury to patients at this period comes from going out too early. Usually the temperature is subnormal for several days—a circumstance due to the weakness of the patient—and so long as this condition obtains the patient is highly susceptible to a chill. Hence it is a good rule not to allow exposure to the external atmosphere until the temperature has been normal for several days. The diet should now be more liberal, and tonics, such as gentian, iron, and quinin, may be administered and continued until complete restoration of the patient's health has taken place. In every way possible exposure to reinfection during the period of convalescence is to be avoided. The sequelæ must be treated according to general rules.

DENGUE.

(Break-bone Fever.)

Definition.—An acute infectious disease occurring epidemically in tropical and subtropical countries. Its chief symptoms are—a double febrile paroxysm (separated by an interval), arthritic and muscular pains, and a skin-eruption in about one-half the cases.

Historic Note.—The disease was prevalent in Java as early as 1779, in India in 1824, and later in the West Indies, Spain, and in some of the southern American States. Mild epidemics have visited Philadelphia, New York, and Boston (during warm weather), but, as a rule, it has not traversed regions beyond 32° N. latitude.

Its *pathology* has not been studied, death being the rarest of events.

Etiology.—McLaughlin, of Texas, has isolated from the blood and cultivated a micrococcus. H. Graham¹ has discovered an ameboid form resembling the *plasmodium malariae*, but having a longer life-cycle.

Predisposing Factors.—Its prevalence is favored by the summer season, and to a slight extent by faulty hygienic conditions. On the other hand, age, race, sex, and social status are all without effect, most persons being susceptible, a fact that accounts for its marvellously rapid diffusion. As a rule, susceptibility is exhausted by one attack. The epidemics spread along lines of travel by land and sea. Graham's experiments in Beirut indicate that dengue is not contagious, but *culex fatigans* may carry the infection from one person to another. Altitude is said to exercise an inhibitory influence.

Clinical History.—There is a period of *incubation* that lasts from one to four days and exhibits no prodromes.

Invasion then is *abrupt*, with a slight chill; fever follows, the temperature reaching its maximum—103° to 106° F. (39.4° to 41° C.) or over—at the end of the first or on the second day, and is accompanied by headache and by muscular and arthritic pains. The patient's sufferings are intense, the *pains* being described as “breaking”—a peculiarity to which the disease owes the popular name of “*break-bone fever*.” The painful *joints* are neither swollen nor tender, as a rule. Jones reports an epidemic in which severe pain was absent. The *respiration* and *pulse* are much quickened; there is anorexia and slight nausea. Febrile albuminuria is rare, delirium and mental torpor also; but *prostration* may become marked, and an *erythematous eruption* (*initial rash*) commonly appears. DeBrun² noted the symptoms during the epidemic at Beirut (1892), and states that the eruption is roseolar, morbilliform, scarlatinous, or papular. He distinguished three groups of cases: 1. With high fever and marked associated symptoms, and with eruption. 2. Fever absent, the symptoms mild, with eruption. 3. The eruption the only symptom. The eruption may appear early, but has no fixed time, is evanescent in mild cases, and is never constant in character. It is attended with burning and itching, and DeBrun noted desquamation. *Hemorrhages* from the various organs (nose, gums, stomach, bowels, lungs, kidneys, etc.) may occur, and reach even a dangerous extent. The *lymphatic glands* are often swollen; the mucosæ of the nose and throat are hyperemic; the eyes are congested and the face flushed. The disease is characterized by well-marked leukopenia.

¹ *Medical Record*, Feb. 8, 1902.

² *Rev. de Méd.*, No. 6, 1894.

The *initial fever* lasts three or four days, and ends with a deep remission accompanied by sweating. All the symptoms now vanish save a slight soreness and stiffness, but after two or three days the characteristic symptoms (including a roseolar eruption) reappear. This terminal eruption is rubeolar, commencing on the palms and backs of the hands, and extending upward. It is circular, dusky red, and sometimes slightly elevated. It extends quickly to other parts, being best seen on the back, chest, upper arms, and thighs. The spots disappear on pressure, and never or rarely become petechial (Manson). The *second* febrile paroxysm is usually milder and shorter than the first.

The **duration** of the disease is from seven to ten days, the attack being followed by a slow convalescence, which may be interrupted by a relapse. The slowness of the recovery is due to persistence of the pains, mental depression, and marked physical prostration.

Complications.—Meningitis has been rarely noted. Convulsions sometimes occur in children, and severe catarrhal inflammations of certain mucosæ (bronchial, gastric) may develop. Insomnia is common. Hyperpyrexia and pericarditis occur, though exceptionally.

Diagnosis.—The diagnosis of the epidemic form of the disease is an easy one after observation of the first few cases, but it is difficult to discriminate sporadic cases from *rheumatism*. The course of the fever, however, differs in the two diseases, while the eruption belongs to the former alone. *Influenza* may resemble dengue. Influenza occurs in the cold season, and herpes is usually the only eruption; the joints are rarely involved; there is no recurrence of the fever, and serious complications are more frequent. The discovery of the bacillus of influenza is decisive, and the existence of an epidemic of either condition suggests the true nature of the disease. *Scarlet fever* has an erythematous eruption, but the fever is continuous, angina is present, and the arthritic symptoms are wanting. As a rule, dengue prevails only in tropical and subtropical countries.

Yellow fever has been mistaken for dengue, and the two affections may prevail together, as in the Galveston epidemic of 1897. The differential diagnosis is difficult, as there are points of similarity—time of appearance, geographic distribution, and the character of the febrile paroxysm. To show contrast, however, I have arranged the following table:

| DENGUE. | YELLOW FEVER. |
|--|--|
| Affects all races. | Foreigners more especially. |
| Facies characteristic; face flushed. | Mucous membranes injected. |
| Irregular rise of fever, followed by remission, then a second moderate rise. | The temperature rises regularly. Duration of fever 72 hours. |
| Duration 5 to 9 days. | |
| The pulse keeps pace with the fever. | Pulse falls while the fever is rising. |
| Eruption frequent (terminal rubeola). | Eruption quite rare. |
| Vomiting rare. | Vomiting frequent. |
| Urine never contains albumin (?). | Urine early albuminous. |
| Jaundice absent. | Jaundice present and early appearing. |
| Hemorrhages from mucous outlets, generally slight, and black vomit rare. | Hemorrhages common and severe. |
| Muscular and joint pains present. | Black vomit an alarming symptom. |
| Prognosis favorable. | Absent. |
| Serum-diagnosis valueless. There is a well-marked leukopenia. | Often fatal. |
| Second attacks common. | Serum-diagnosis present in 66 per cent. of cases; no leukopenia. |
| | No second attacks. |

The **prognosis** is, with rare exceptions, favorable, dangers arising only in the serious forms, particularly those showing hemorrhages.

Treatment.—Indications: (a) to harbor the patient's strength, and (b) to meet certain leading symptoms. The first is to be met by enjoining rest in bed, by a generous diet, and by the use of stimulants and tonics during convalescence. The fever may demand treatment, and when this is high, hydrotherapy is indicated. For the intolerable pains morphin is to be administered hypodermically. Efforts to destroy the *Culex fatigans* should be instituted. Isolation should be practised.

THE PLAGUE.

(*Bubonic Plague; Black Death.*)

Definition.—A specific contagious disease, occurring chiefly in unsanitary surroundings and characterized by high fever and cutaneous symptoms (petechiæ, etc.). Its course is severe and rapid, and it occurs in epidemics.

Historic Summary.—An Oriental disease, the plague, has long been endemic in certain portions of India. Most European countries have in the past been visited by epidemics of the malady, and among the most famous was the truly pandemic prevalence of "black death" in Europe during the fourteenth century. Another virulent outbreak occurred in London in 1665, destroying more than 70,000 persons. In May, 1894, a severe epidemic prevailed in Canton and Hong-Kong, to which cities it had been imported from Northern India. In September, 1896, the plague appeared in Bombay and the Bombay Presidency; in November, the disease, "which had seemed to be abating, revived" (Willoughby). Since then the plague has shown periods of decrease followed by others of decided increase, and the total plague-statistics for the Bombay Presidency from September, 1896, to January 13, 1899, are 214,197 cases and 169,240 deaths. In the autumn of 1899, 2 cases were brought to the New York harbor, and on March 6, 1900, it appeared in the Chinese quarters of San Francisco, and 31 cases were officially reported between that date and February 13, 1901. It has reached several European ports—Oporto, Hamburg, Glasgow, London. W. J. Simpson¹ has given a graphic account of the history and distribution of the plague.

Etiology.—**Bacteriology.**—During the epidemic at Hong-Kong, Kitasato and Yersin, working independently (1894), discovered the special organism of the plague (*Bacillus pestis bubonicæ*). It stains deeply at the ends, giving the appearance of a pair of micrococci, but is really a short rod-bacillus with rounded ends. Pure cultures can be made, and when animals (mice, rats, guinea-pigs, rabbits) are inoculated with these the symptoms of the disease are produced.

Predisposing Causes.—These are (a) unhygienic conditions, and (b) seasons—summer and early autumn.

Inside the body the bacillus has been found in the lungs (plague-pneumonia—where it is often combined with the pneumococcus and staphylococcus), in the enlarged glands, in the pus from the buboes (in large numbers), and the blood. *Outside* the body, among infected materials are dust, plague-infected flies, fleas, the excreta, food, and soil.

¹ "A Treatise on the Plague," 1905.

Modes of Transmission and Entrance into the Body.—According to Kitasato, the bacillus enters either through the digestive (rare) or respiratory tract or the skin (*e. g.*, abrasions of the feet). The point of infection is usually a gland or group of glands (Flexner) causing the primary bubo. The bubonic pest is spread by two principal factors—the rat and man (Simond). In most outbreaks of human plague rats had the disease both before and during the epidemic (Clemow). The rat is the carrier from house to house; man is the ordinary agent of transport for long distances. Flies, fleas, ants, and other insects may act as carriers from rat to man. The rat flea carries the contagion from one rat to another. Nuttall's studies indicate that transmission of the poison by stinging insects is extremely rare. Certain animals besides rats (mice, dogs, cats, rabbits, pigs, horses) may become infected and transmit the disease to healthy animals. McCoy and others have found the plague bacillus, which was proved to be pathogenic for rats and guinea-pigs, in the ground squirrel. Yersin established the contagion of plague by keeping inoculated rats and healthy mice in the same place (Payne, in Allbutt's *System*). The disease is commonly transmitted by foci of the infection (houses, ships), by fomites, and possibly by plague-infected food.

Clinical History.—**Varieties.**—The classification is based on the particular system of the body principally invaded as follows: (a) Bubonic (glandular); (b) septicemic (circulatory); (c) pneumonic. Formerly two distinct forms, (1) *pestis minor*, or larval plague, and (2) *pestis major*, or the severe epidemic form, were recognized.

Incubation.—This lasts from two to five or, rarely, eight days. In malignant epidemics it may be but three or four hours. Prodrómata may be observed for from twelve to twenty-four hours; they are intense headache, vertigo, and an unsteady gait. The physiognomy is stupid.

(a) **Bubonic Type.**—This type corresponds to the so-called *pestis minor* (see *ante*). It often appears as a fore-runner of severe epidemics. It is characterized by swelling of the lymphatics lasting about a fortnight with slight general disturbance, as a rule. The bubonic, however, may merge into the septicemic or pneumonic forms, and here may be mentioned certain symptoms which are common to all varieties; they are halting speech, staggering gait, great prostration, a peculiar physiognomy, and more or less lymphatic involvement.

(b) **Septicemic Type.**—Invasion may be abrupt; less commonly it is preceded by the prodromes mentioned above; and rarely, bilious vomiting or hematemesis are the ushering-in symptoms. A prolonged rigor or repeated shiverings occur. The temperature does not rise to a high level (100° F.), owing to profound prostration, and the pulse becomes rapid and thread-like, although variable in force and character. Delirium or coma tends to supervene. Debility may now be extreme, and the patient may die in the initial period. More commonly this threatened collapse is survived, and then (second to the fifth day) the most characteristic feature almost always appears—secondary buboes or inflammation of the lymph-glands, most commonly the inguinal, but also the axillary and cervical. The latter enlarge and are painful. Resolution may occur, or they may remain unchanged, particularly in fatal cases. Suppuration may also occur, and rarely gangrene, forming the so-called carbuncle.¹ Petechiæ and the hemorrhagic diathesis, as shown by bleedings from the

¹ Saunders' *Year-Book*, 1902, p. 378.

lungs, stomach, and intestines, arise in the worst forms. In this variety blood obtained by puncture of spleen, liver, and other organs shows the microbe in pure culture.

(c) **Pneumonic Type.**—Pneumonic plague, where primary localization of the disease in lungs occurs, commences with a rigor, malaise, headache, nausea, vomiting, and pains in the limbs. Fever, varying in range from 102° to 105° F., hurried breathing with oppression, cough, and blood-tinged sputum, soon appear. The physical signs, especially the stethoscopic, may be those of bronchopneumonia. The local symptoms grow worse, cyanosis, delirium, and later coma supervene, while the heart's action fails and death occurs on the third, fourth, or fifth day of the illness. In cases which recover or become more protracted, buboes may appear, and rarely these develop early in plague pneumonia.

(d) **An intestinal type**, with marked hematemesis, bloody diarrhea, and abdominal pains, also occurs.

(e) **Abortive Type** (*Pestis Ambulans*).—Certain epidemics are distinguishable by the larger proportion of mild cases (Manson). The patient may be so little inconvenienced as to be able to be about throughout the illness.

Plague pneumonia may also be secondary to, or symptomatic of, other types, the microbe having reached the lung metastatically, or possibly has been inhaled into the lungs. This form likewise simulates lobular pneumonia in its clinical features, and a pure growth of the plague bacillus can be obtained on making cultures from the sputum.

Sequelæ.—Paralyses of various kinds, myocardial weakness, and recurring suppuration of buboes are the principal sequelæ of the disease.

Relapses rarely occur, and are dangerous.

Diagnosis.—The diagnosis can be made with ease and certainty when the disease occurs in endemic centers, but when it occurs elsewhere its recognition offers some difficulty. The bubonic type is easily recognized, as a rule. On the other hand, to differentiate between primary plague pneumonia and ordinary lobar or bronchopneumonia is puzzling. A certain diagnosis rests upon bacteriologic evidence alone.

Prognosis and Mortality.—The death-rate is high, ranging from 40 per cent. (rare) to 80 or even 90 per cent. Among favorable indications is suppuration of the buboes. On the other hand, a rapid disappearance of a group of swollen glands is a bad augury. Additional unfavorable indications are plague-pneumonia, intense toxic features, with cardiac dilatation, purpuric spots ("tokens"), and hemorrhages.

Treatment.—**Prophylaxis.**—The precautions to be taken by the individual relate to the abandoning of all unsanitary habits, the isolation of the sick, and the avoidance of prolonged contact with infected patients or dwellings. Personal cleanliness and freedom from abrasion of the lower extremities are important prophylactic measures (White). It would seem that doctors and even nurses and attendants in well-ordered and properly ventilated hospitals rarely take the plague.

The prophylaxis of the public embraces—(a) Isolation of the sick and thorough disinfection of the sick-room, the bed and bed-linen, the vomitus, and the stools. Kitasato advocates steaming the bed at 212° F. (100° C.) for one hour, or exposure for a few hours to sunlight, and the burning of all infected articles. "After recovery the patient is to be kept in isolation for at least one month." Cases of *pestis ambulans* must be found and treated on account of their bearing on the spread of

the graver types. The infected houses are to be thoroughly disinfected, and a pure water-supply procured. (b) Protective inoculation or treatment by "vaccination" of healthy persons seems efficient. Haffkine,¹ in a recent report, states that at Hubli practically all of 50,000 inhabitants were rapidly inoculated. The difference in mortality of those inoculated and of those uninoculated averaged from 80 to 90 per cent. The dose was 2.5 c.c. Calmette recommends Yersin's antiplague serum for prophylactic purposes in preference to Haffkine's vaccine. Strong advocates the injection of attenuated living cultures of *Bacillus pestis* as a method of immunization. Buchanan² advocates the keeping of cats to destroy the root of the trouble—the rats.

Treatment of the Attacks.—The diet should be liquid and nourishing, while free stimulation is demanded from the onset. *Medicines* are used to combat symptoms as they arise. Delirium and pain are to be met by morphin or hyoscin, and high temperature by hydrotherapy.

Local Treatment.—Cantlie does not believe in local measures before suppuration occurs, although he has observed good results to follow injections of mercuric chlorid and potassium iodid.

Serum-therapy.—Anti-plague serum exercises a specific action (Yersin). Of 26 cases treated, 2 died—a mortality of 7.6 per cent. Calmette³ states that serum injection provokes rapid destruction of the bacilli by phagocytosis. As a curative dose, 20 c.c. must be injected intravenously, and repeated in twenty-four hours if there be fever still. Choksys concludes that in the Yersin-Roux antiplague serum we possess an efficacious remedy, especially if used during the first few or even twenty-four hours, serious complications being averted.

ERYSIPELAS.

(*St. Anthony's Fire.*)

Definition.—A specific, acute contagious disease, characterized by a special inflammation of the skin and subcutaneous tissues, with a tendency to spread, high fever, moderate prostration, a disposition to mixed infection, and an average duration of fourteen days. It usually occurs as an endemic disease, though also in epidemic form.

Pathology.—Erysipelas is a specific inflammation involving the skin, subcutaneous and less commonly the mucous surfaces. When inflammation extends to the subcutaneous connective tissue there follows, as a rule, suppuration. The specific cocci are found in the superficial lymph-vessels and spaces of the affected skin. Beyond the border of the inflamed region they occupy chiefly the lymph-vessels, where they are finally overpowered by the phagocytic leukocytes. Microscopic examination reveals the changes of simple inflammation. Pericarditis, endocarditis (rarely malignant endocarditis), pleuritis, and nephritis may be noted.

Etiology.—**Bacteriology.**—The specific cause of the disease is the *streptococcus erysipelatis* of Fehleisen, which is identical with the ordinary pus-producing streptococcus. Petruschky has shown that streptococci derived from non-erysipelatos morbid processes in man were capable of producing a typical erysipelas. The streptococci of

¹ *Proc. Roy. Soc.*, vol. lxx., No. 418.

² *British Med. Jour.*, May 30, 1908.

³ *Lancet*, 1454, Nov. 17, 1900.

erysipelas is a saprophytic organism; it assumes the form of a serpent or chain and are very small, somewhat variable in size, and thrive on all kinds of culture-media. Their favorite situations are the lymph-vessels of the skin and the cutaneous connective tissue. They are especially abundant and active near to the advancing border of the erysipelatous area, but are rarely found in the blood-vessels, and in blood-serum they are caused to disappear by the action of the phagocytes; yet in exceptional cases intra-uterine infection has occurred. G. E. Pfahler¹ found a diplococcus in 8 cases. Erysipelatous inflammation can also be produced experimentally by the staphylococcus.

Predisposing Causes.—(1) **Season.**—In a paper on "Seasonal Influences in Erysipelas, with Statistics,"² I have shown, as the result of an analysis of 2010 cases collected from different sources that the various seasons of the year exercise a potent influence upon the frequency of this affection. Thus month by month the cases increase, in slightly varying ratio, from August to April, the latter month giving the greatest number, and then there is a rapid decrease from April to August, when we find the smallest number. Again, one-half of all the cases occur during the months of February, March, April, and May, and 15.9 per cent. during the month of April alone. It was found that a low barometer and mean relative humidity invariably correspond with the annual period in which the greatest number of cases occur, and that the highest percentage of relative humidity corresponds with the months affording the fewest cases.

(2) **Age.**—From the notes of 1894 cases I found that in 25.8 per cent. the age of the patient was between twenty and thirty years. After fifty years the cases decrease rapidly, and more than 15 per cent. occur before the age of twenty. The great liability of newly-born infants is well known.

(3) **Sex.**—This factor was noted in 1767 cases, and a marked preponderance of the male over the female sex was noted (about 3 to 2).

(4) **Previous Attacks.**—Of 450 cases, there had been previous attacks in 39 (8.6 per cent.), in one instance four, and in another seven, while second and third recurrences were not uncommon.

(5) **Family predisposition** exercises a slight though decided influence.

(6) **Certain Antecedent Affections.**—Dr. M. Booth Miller examined the history of 301 cases, and found that acute coryza preceded the attack in 13 instances. Slight lesions of the Schneiderian mucous membrane may be assumed to exist in such instances. Testimony confirming the well-known fact that certain chronic diseases (chronic Bright's, phthisis, organic heart disease, chronic alcoholism) augment a receptivity to the complaint has also been brought to light by my researches. Cheadle has seen 5 fatalities in cirrhosis of the liver from erysipelas.

(7) **Slight Injuries, Abrasions, etc.**—Erysipelas will not develop on a surface which does not present a break, but with this present may do so though the latter be so trivial as to escape observation. Slight abrasions and fissures, either in the mucous membrane of the nose or in the skin of the face or ear, as well as all forms of slight injuries, are liable to furnish a highway for the organism. Yet in 643 out of the 2010 cases mentioned above, previous lesions were noted in but 13. Women who have been recently delivered and persons subjected to surgical operations are peculiarly liable, and any deep-seated focus of irritation (necrotic bone, chronic abscess, appendicitis) may give rise to erysipelas.

¹ *Phila. Med. Jour.*, January 13, 1900.

² *Proc. of the Amer. Climatolog. Assoc.*, 1893.

(8) **Antihygienic Surroundings.**—These doubtless predispose to the affection, as has been shown by the prevalence of erysipelas in hospitals and institutions in which the sanitary arrangements were markedly faulty.

Modes of Conveyance of the Contagion.—The latter may be air-borne for short distances at least. It has been collected from the air of rooms and wards occupied by erysipelas patients. It may also be transferred for a longer or shorter distance by fomites, by instruments, unclean hands, etc. The infecting microbe is inoculated through small and even invisible lesions of the skin about the nose and mouth (spontaneous or facial erysipelas). It is possible that intravascular infection may occur.

Clinical History.—I shall discuss only *idiopathic* erysipelas, the traumatic variety falling within the domain of surgical treatises.

Incubation.—This is somewhat varied, though it ranges usually from seven to fourteen days. The *prodromal symptoms* are, for the most part, general in character, consisting in headache, restlessness, cough and sore throat, anorexia, and slight or moderate pyrexia. These endure for a very variable period—from a few hours to several days.

Invasion Stage.—The symptoms are (1) local and (2) general.

(1) At first the affected part feels hot, tense, painful, and is tender to the touch. A circumscribed area becomes red, swollen, firm, and shining, and simultaneously the subjective symptoms (pain, heat, etc.) become aggravated. The *point of election* is usually on the nose, but it may be on the ear, the face, or elsewhere about the head. The inflamed, swollen zone spreads, chiefly in the direction of one or the other side of the head. Separating the diseased from the unaffected skin there is a sharp line of demarcation—an elevated brawny ridge; this ridge presents a “zigzag irregularity of outline, like the burned edges of a sheet of paper” (Warren). While the inflammation is advancing there may be noted, beyond the border of the latter, little red streaks and spots that grow in area till at last they become confluent. Any natural prominence or fold in the integument may prevent extension of the inflammation (*e. g.*, nasolabial folds). In cases of *average severity* the face is much swollen, the eyes closed on account of tumefaction of the eyelids, the ears greatly enlarged (better marked on one side than the other), the scalp swollen and tender, and the facial lineaments often changed beyond recognition. Tenderness to pressure is a constant feature. In a minority of the cases the inflammatory process extends from the head to the arms, to the trunk, and even to the lower extremities (*erysipelas migrans*), and in such instances the face may be healed while the disease is yet extending. When the disease is arrested the peripheral ridge ceases to extend and grows pale.

The epidermal layer may become elevated over circumscribed areas, giving rise to larger or smaller vesicles or bullæ (*erysipelas vesiculosum*). Suppuration may attack these large vesicles, whereupon they fill with pus (*erysipelas pustulosum*). From intense infiltration the part or parts may become gangrenous—*erysipelas gangrænosum*. Enlargement of the cerebral lymph-glands is common. Desquamation follows erysipelas, and the complexion is more delicate than before the attack.

(2) **General Symptoms.**—With the *onset* of the attack the patient is seized with repeated fits of chilliness; less commonly, a severe rigor occurs. Immediately, and more rapidly than before, the *temperature*

risers to a height of 104° or 105° F. (40°–40.5° C.) on the evening of the first day. As a rule, the temperature reaches its maximum (105° to 107° F.—40.5° to 41.6° C.) on the third evening. Marked nocturnal remissions of temperature (2° to 5° F.—1.1° to 2.7° C.) after a few days of continued fever, are the rule, but the evening temperature may in rare instances be to an equal degree lower than the morning. At the end of a week the temperature declines rapidly to normal, *i. e.*, by crisis. Sometimes, however, the course of the fever is prolonged and defervescence may be less critical (lysis). In erysipelas migrans a long and decidedly irregular temperature-curve is presented, and the same remark applies when complications are present. The *pulse* is frequent, of good volume, and soft. I have been able to confirm the observations of Da Costa, Strümpell, and others that the cutaneous inflammation in erysipelas (particularly erysipelas migrans) may advance to a slight extent even after the temperature has returned to the normal grade.

The *tongue* is furred, the anorexia intensified, and nausea and vomiting occur. The *bowels* are usually constipated, though I have observed instances in which marked diarrhea developed at a late stage. The inflammation may extend to the mucous membrane of the throat and larynx, causing swelling and edema of the parts. It may also involve the serous membranes, though rarely. The *nervous symptoms* are intense headache and restlessness, with some mental aberration at night. Actual nocturnal delirium appears in the severer forms, and in drunkards delirium tremens may suddenly develop. The *urine* presents the usual febrile characters. Commonly it contains a little albumin, and rarely acute nephritis occurs as a complication. A polymorphonuclear leukocytosis, parallel with the severity of the infection, occurs in erysipelas. The blood, however, must come from the warmed finger (Chantemesse and Ray¹).

There is a direct correspondence between the intensity of the local and constitutional disturbances in this disease. Often in severe forms (such as are apt to arise in old, much enfeebled, or intemperate persons) of facial erysipelas the *typhoid* (adynamic) *condition* is developed.

Complications and Varieties.—An analysis of 1674 cases of erysipelas with particular reference to complications gave an interesting series of results, and one at variance with the notions of most authors. Some are given here in the order of frequency of occurrence: Abscess, 105; rheumatism, 20; delirium tremens, 10; lobar pneumonia, active delirium, phlebitis, pleurisy, each 7; acute nephritis, 6; synovitis and diarrhea, each 5; tonsillitis, 3; catarrhal pneumonia, otitis media, edema of the larynx, acute bronchitis, each 2.² Some of these conditions are septic in nature and due to the primary infection.

The fact that acute articular rheumatism is a relatively frequent complication of erysipelas is worthy of special notice, for the reason that the attention of the profession has not hitherto been called to it. The symptoms of rheumatism usually come on several days after the onset of erysipelas. In a few instances pneumonia appeared early, being due most probably to special localizations of the specific streptococcus. To such cases the term "pneumo-erysipelas" may be appropriately applied. The cases—2 in number—in which acute nephritis developed during the first

¹ *Presse méd.* July 1, 1899; *Saunders' Year Book* for 1901.

² "The Complicating Conditions, Associated Diseases, and Mortality-rate in Erysipelas," by the author: *The Int. Med. Mag.* for Oct., 1893.

few days of the attack should in like manner be termed "nephro-erysipelas." Meningitis was present in a single instance only.

Three other forms—namely, *phlegmonous* or cellulo-cutaneous, *relapsing* erysipelas, and *erysipelas neonatorum*—should be mentioned. The first exhibits an inflammation of the subcutaneous tissue, which tends to suppurate. Relapsing erysipelas constitutes the chronic form of the disease, recurring at intervals, and usually in the same locality. It is commonly due to some deep-seated focus of suppuration. Erysipelas neonatorum is the result of infection of the stump of the umbilical cord. From the navel the inflammation spreads to the thighs and genitals. As a rule, there is fever, followed in a few days by fatal collapse.

Sequelæ.—The hair often falls, but it is usually replaced by a fresh crop. Otitis media and chronic nephritis may date from an attack of erysipelas. *Per contra*, erysipelas is reputed to be curative of certain affections (eczema, lupus, carcinoma, sarcoma).

Out of 476 cases collected by me relapses occurred in 54 (11.3 per cent.), and in 1 of these instances 5 relapses occurred; in 2 others, 4.¹

The **diagnosis** is made with ease after the eruption has fully developed, and its appearance, seat, and behavior, particularly the manner of extension of the brawny, ridge-like edge (best marked on the forehead), are the features that distinguish it from every other disease. A bacteriologic diagnosis is often possible, the streptococcus being found in the pus and secretions from the naso-pharynx.

Differential Diagnosis.—*Erythema* produces superficial redness, but is not attended with heat, swelling, or fever. *Urticaria* assumes the form of pale-red circular wheals, which cause marked itching and appear in successive crops, often disappearing in the course of a few hours. *Acute eczema* of the face, when intense, may resemble erysipelas; but it lacks the peculiar border and mode of progression so characteristic of the latter disease. Again, eczema produces troublesome itching, and the swelling is less than in erysipelas. *Chronic erythematous eczema* is met with later in life, is without fever, without any considerable swelling or pain, and excites intense itching. *Eczema nodosum* is characterized by its nodosities near the joints.

Course and Duration.—In my own experience, based upon 1880 cases,² the average duration (including the prodromal stage and period of convalescence) in persons under forty years of age is fourteen days. The course of the disease is much lengthened by complications, the pre-existence of chronic affections, and by age (after the fiftieth year).

The **prognosis** is favorable, and it is rare for erysipelas to assume a malignant type. Perhaps the chief dangers lie in certain complications, especially extensive suppuration, pneumonia, acute nephritis, delirium tremens, etc. Acute articular rheumatism is comparatively harmless; but *previous debility*, especially if dependent upon chronic diseases, as syphilis, chronic rheumatism, gout, tuberculosis, organic disease of the heart, and the like, increases the percentage of deaths considerably. Again, age has a positive influence upon the mortality, which it augments moderately after the forty-fifth year, and most decidedly after the sixtieth

¹ *Journal of the American Medical Association*, July 22, 1893, by the writer.

² "Points in the Etiology and Clinical History of Erysipelas," by the writer: *Journal of the Am. Med. Assoc.*, July 22, 1893.

year. Of 2663 deaths due to erysipelas (United States Census Report), the death-rate per 100,000 inhabitants was as follows: under 5 years, 31.84; 5 to 15 years, 0.81; 15 to 45 years, 2.80; 45 to 65 years, 8.88; 65 and over, 38.55 (Wm. L. Rodman). When death occurs it is due to exhaustion.

The *mortality-rate* is low, as shown by the results of my own collective investigations into the subject. I found the general average death-rate to be 5.6 per cent., while in cases from private practice it was 4 per cent. In persons over seventy years it was 46 per cent. The traumatic cases gave a mortality of 14.5 per cent.

Treatment.—The treatment of erysipelas falls naturally into four subdivisions: (1) *Dietetic*; (2) *Constitutional*; (3) *Local*; (4) *Prophylactic*.

(1) **Dietetic.**—Proper attention to the diet is of the first importance. It must be generous and composed of highly nutritious articles, and if the temperature be high, only liquid forms of nourishment should be administered in definite quantities and at stated, brief intervals. Rectal alimentation should be resorted to if the stomach rejects a suitable dietary. Lack of attention to the patient's diet during the primary attack tends to increase the frequency of relapse. In persons over fifty years of age, and in those in whom the vital processes have been lowered on account of previous chronic diseases, correct alimenation is of paramount importance, often abridging the course of the affection.

(2) **Constitutional Treatment.**—When, despite an appropriate diet, the pulse becomes very rapid and feeble, the heart's first sound indistinct, and the tongue dry or brown, indications for the use of stimulants are present and must be heeded. Alcohol may be given with a comparatively free hand, 12 to 16 ounces (360.0–480.0) of whisky daily in divided portions. Strychnin gives prompt results, and digitalis may be used in severe cases. In marked gastric irritability champagne is to be preferred.

The eliminative organs, especially the kidneys, are to be stimulated, so as to rid the economy of the bacillary toxins.

The tincture of the chlorid of iron was first extensively used in this disease by English authorities, and was formerly regarded by most clinicians as a truly specific remedy. In 74 cases of erysipelas which were treated by this remedy alone, the average quantity being 1 dram (4.0) daily in divided doses, in the Pennsylvania Hospital by Drs. Lewis, DaCosta, Longstreth, Meigs, and others, the death-rate was 4 per cent.¹ Other preparations of iron, however, are equally efficacious. Quinin is a valuable remedy in erysipelas, and during the past twelve years I have employed it in not less than 30 cases, confining its use to instances in which the temperature touched 103° F. (39.4° C.), and, with a single exception, in uncomplicated cases (22 in number) the nocturnal remissions were decidedly greater. In every instance iron in some form was administered simultaneously. Numerous *antiseptic* remedies have been recommended.

Antistreptococcus Serum.—André, Robinson, Cox, Anderson, and others have reported instances of its successful use. The serum is injected subcutaneously; its influence endures over several days, but it is important that the injections are repeated at forty-eight-hour intervals. Marmorek's serum (care being taken that it is not too old) is to be preferred, and it is probable that it has immunizing power as well as a specific action as a curative agent. The serum treatment is to be encouraged.

¹ "The Treatment of Erysipelas," by the writer, *Therapeutic Gazette*, July 16, 1894.

Certain *symptoms* demand internal medication. When the fever is high, its reduction is best accomplished by means of cold spongings combined with the ice-cap, or cold or gradually cooled baths. Guaiacol applied externally has recently been employed for the same purpose.

For *marked nervous phenomena*, such as pain, sleeplessness, and active delirium, hyoscin hydrobromate (gr. $\frac{1}{100}$ —0.0006) has been tried hypodermically at the Medico-Chirurgical, Pennsylvania, and Philadelphia hospitals, and has given promise of being a valuable remedy. It should not be employed when the heart-power is deficient. For the same indication we may utilize the following: Sodium bromid, gr. v (0.324) every two hours, or gr. xx—xxx (1.296—1.944) at night; morphin, gr. $\frac{1}{8}$ (0.008), and chloral, gr. x (0.648), in combination every half-hour for three doses; potassium bromid, gr. x (0.646), and tincture of cannabis indica, ℥ x (0.666), in combination, and morphin, gr. $\frac{1}{8}$ (0.0108), hypodermically.

The treatment of the various *complications* must be conducted in accordance with general principles applicable to each.

3. **Local measures** have always held a prominent place in the treatment of erysipelas. In my paper previously cited those most frequently used were elm (37 cases); lead-water and laudanum (20 cases); carbolic acid (1 : 40), injected subcutaneously (18 cases); zinc oxid (14 cases); mercuric chlorid solution (14 cases); ichthyol ointment with lanolin (8 cases), etc. P. Ph. Smolitcheff,¹

R_y. Tr. iodi,
Ol. camphor,
Ichthyoli,

25.0 grams;

āā 12.5 grams.—M.

Sig. For external use. Shake before applying.

Many of these preparations were prescribed for their effect in excluding the air—a leading indication. This I am in the habit of meeting by the use of carbolized vaselin or cool carbolized oil. Collodion and ichthyol-collodion (strength 10 to 50 per cent.), painted over the erysipelatous area and also over the surrounding healthy skin for 2 or 3 cm. has been much advocated.

Tucker² recommends the application of a saturated solution of magnesium sulphate in water. This is applied in facial cases on a mask consisting of from fifteen to twenty thicknesses of ordinary gauze, of sufficient size to extend beyond the area involved, with a small opening to permit breathing, but none for the eyes. After thorough saturation with the solution, the mask is applied and covered with oiled silk or wax paper; it is wetted often enough to assure a moist dressing—usually every second hour. The dressing should not be removed oftener than once in twelve hours to permit an inspection of the parts.

A knowledge of the microbic nature of erysipelas has led to the local application of numerous antiseptic remedies. Mention has been made of the method of injecting carbolic acid. Here the aim is to check the spread of the inflammatory process by inserting the needle at numerous points just beyond the inflamed border. The method (introduced by Heuter) has been much practised by Henry at the Philadelphia Hospital, and is especially applicable in erysipelas migrans. In the statistics before given a solution of mercuric chlorid (1 : 4000) was used locally in 14

¹ *Medical News*, Nov. 14, 1903.

² *Therapeutic Gazette*, June 15, 1908.

instances, to which I can add the results of 12 others at the Medico-Chirurgical Hospital and in private practice. In a few cases it was injected beneath the skin, as in the case of the carbolic acid. More recently it has been recommended to scarify the affected part and follow with the application of a solution of mercuric chlorid. In view of the fact that the streptococcus is found chiefly in the more superficial channels of the corium, it follows that it may be attacked directly by the mercuric chlorid solution when the latter is used after scarification; and this method of treatment is at once most promising and rational. G. L. Curtis¹ advises sodium sulphate, which acts by depriving the germs of oxygen, as a local application. MacLennan advocates a saturated solution of picric acid as a local remedy.

(4) **Prophylaxis** embraces isolation and care of the skin of the whole body. Bathing with a boric-acid wash (3 per cent.), at intervals of several hours, so as to disinfect the desquamating epidermis, removes a source of danger. It is probable that relapses are sometimes due to autoinfection. Frequent change of the body-linen is to be advised and removal to another room during convalescence may prevent a relapse. Admission of erysipelatos patients to hospitals should be refused, except such institutions be provided with an isolation building.

DIPHTHERIA.

(*Diphtheritis; Angina Maligna; Croup.*)

Definition.—An acute, contagious disease caused by the Klebs-Löffler bacillus, and characterized, anatomically, by a croupous-diphtheritic faucitis, less commonly rhinitis and laryngitis. Clinically, it is characterized by irregular fever, prostration, and albuminuria; also by the secondary development of toxemia, and often cardiac failure. It is commonly followed by peculiar paralyses. In large municipalities it behaves endemically, and from time to time epidemically. The disease, however, is less prevalent than formerly.

Pseudo-diphtheria.—There are forms of inflammation occurring most frequently in the pharynx and adjacent air-passages (and also in many other parts of the body) that are attended with the formation of a pseudo-membrane, and are not caused by the Klebs-Löffler bacillus. These cases have been studied exhaustively by Prudden and others, who have usually found the streptococcus. The latter, however, has been found in the inflamed mucous surfaces met with in erysipelas, scarlatina, and measles. Vincent's angina is a form of pseudodiphtheria.

Pathology.—The true diphtheritic inflammation has for its chief pathologic peculiarity the production of a fibrinous exudate. When the inflammation is superficial and of a mild grade, a croupous membrane is produced which can be easily removed from the mucosa, which it covers. In the severer types of the affection, however, the fibrinous membrane infiltrates all the layers of the mucosa, which undergoes necrosis more or less nearly complete. In the severest forms the submucous layer may also become necrotic. It is to be borne in mind that the production of the fibrinous exudate in diphtheria is always preceded by coagulation-

¹ *Med. Record*, April 20, 1901.

necrosis of the epithelium. The membrane-formation is accompanied by changes in the underlying tissue which represent a combination of degeneration and exudation (Councilman, Mallory, and Pearce). The mucous membrane surrounding the exudate is hyperemic, more or less edematous, and the seat of muco-purulent secretions.

The Pseudo-membrane.—Its composition comprises fibrin, pus, disintegrated leukocytes, flakes of necrosed epithelium, bacilli, and sometimes red blood-corpuscles. The fibrin has two main sources: (*a*) "The fibrinogen of the inflammatory matter," which transudes through the capillary walls; and (*b*) Disintegrated, migratory leukocytes, which form branching fibrillæ. Weigert holds that the inflammatory exudation is coagulated by a ferment derived from the disintegrated leukocytes.

The Klebs-Löffler bacilli are found in the meshes of the fibrillæ, in the granular fibrin, and on the adjacent mucous membrane; they are never found growing in living tissue, but always in necrotic tissue. Frequently other micro-organisms are associated (streptococci, staphylococci, etc.). The membrane presents a grayish-white color; it is thick, firm, and adherent, so that its removal entire cannot be effected without great difficulty, and without, as a rule, injury to the surface, as shown by bleeding, etc. The character of the pseudo-membrane is affected by the nature of the underlying structure; thus in the pharynx it is firmer and less easily separable than in the larynx and trachea, where a distinct basement-membrane is found (Flexner). As the membrane becomes older its color is apt to grow darker, becoming yellow or even dark brown. It sometimes becomes gangrenous, and softens or disintegrates, with the production of a very offensive brownish, semiliquid excretion. The advancing edge of the false membrane is usually thin. On the other hand, when the process has become arrested the edge is apt to look raised or wrinkled, and later it may be distinctly curled up.

The membrane may extend downward into the ramifications of the bronchi. In such cases there is apt to be a lobular pneumonia, but the lung may be invaded by the bacillus without any clinical indications. Lung-infection, due to the streptococci and (less commonly) the pneumococci, is common. A generalized bronchitis extending to the smaller bronchi is common from the irritation of aspirated substances. In rare cases the membrane has spread into the esophagus and even into the stomach.

After separation of a croupous membrane repair consists merely in a restoration of the epithelial layer—a process which is initiated by the fragments of epithelium that remain along the edges of the diseased area, and proceeds centrally. On the other hand, in true diphtheria, with necrosis (more or less complete) of the mucosa, sloughing occurs, and the missing structures are replaced by cicatricial tissues.

The Heart.—The muscular structure and the nervous mechanism suffer most. The histologic changes may be of the parenchymatous variety, but only in mild instances; whereas in severer cases fatty degeneration is conspicuous. In still other cases the chief pathologic characteristic is an interstitial myocarditis, and rarely the lesions of pericarditis and endocarditis have been noted. The heart is by no means always involved.

The **spleen** is commonly enlarged, though not to an excessive degree. The **blood** is dark, its coagulability is greatly diminished, and Canon and Frosch have in a few cases found the bacilli in the blood of those dying

of diphtheria. The red corpuscles are somewhat decreased in number during the course of the disease, while the white corpuscles are increased. Bouchut and Dulinsay consider the grade of leukocytosis of prognostic value, and claim that it varies directly with the severity. Grawitz has determined in numerous cases a higher specific gravity of the blood during diphtheria. The **lymphatic glands** of the neck become swollen, as a rule, and are often greatly enlarged, but they show little tendency to suppurate. In pronouncedly septic cases in which a mixed infection is found by culture a good deal of tumefaction of the neck occurs, this sometimes even obliterating the normal contour from jaw to clavicle.

The Kidneys.—The kidneys show degenerative changes, the usual *kidney-lesion* being a hyperemic swelling with edema of the interstitial tissues, and often hemorrhagic spots in the cortex. Sometimes there is a marked glomerulo-nephritis, and rarely a diffuse granular degeneration of the epithelium. Minute areas of necrosis have been observed in the internal organs, in which fibrin has been found deposited (Oertel). Welch and Flexner have produced, by artificial inoculation upon guinea-pigs, kittens, and rabbits, foci of cell-death in the lymph-glands throughout the body, in the spleen, liver, lungs, heart, and intestinal mucosa. When the dose is small and the animal lives several weeks, paralysis may develop.

The **nerves**, in cases of paralysis, have shown parenchymatous and interstitial inflammatory lesions. In paralysis of throat-muscles (*i. e.*, those near the locality of the pseudo-membranous inflammation) the latter show also round-cell infiltration and fatty degeneration of the fibers. The nerve-fibers of the central nervous system may also show fatty degenerative changes. In fatal cases lesions have been found to engage either the meninges, the cerebro-spinal substance, or the nerves.

Etiology.—True diphtheria is caused by the Klebs-Löffler bacillus, and all cases of supposed diphtheria in which the bacillus is absent are to be regarded as non-diphtheritic. The etiologic is, therefore, quite different from the pathologic significance of this term. Recent researches have removed all doubt as to the specific nature of the Klebs-Löffler bacillus.

Bacteriology.—The bacillus diphtheriæ nearly equals in length that of the bacillus tuberculosis, and is twice the diameter of the latter. It has rounded extremities, which are also frequently bulbous, giving it the appearance of a dumb-bell. At times one end only is clubbed, or, more rarely, one or both ends appear pointed. The bacilli are immobile, do not form spores, and stain readily, the best agent being alkaline methyl-blue. Their manner of taking the stain is important. The bacilli show alternating segments of darker and lighter stained areas, and often minute dots showing a most intense and deep staining. They grow on most culture-media, but for clinical purposes Löffler's blood-serum is important (3 parts blood-serum and 1 part neutral or slightly alkaline nutritive bouillon, containing 1 per cent. of glucose). Inoculated on this, they outgrow all other organisms that may be present, and within eight hours or less show numerous spots, one-half to one millimeter in diameter, which have a dull surface and a dense white or somewhat yellowish color. There are usually present also smaller points which have different appearances and which are colonies of other organisms. The former are the colonies of the bacillus diphtheriæ, and from these microscopic preparations and (by further cultivation) pure cultures can be obtained. The bacilli are semi-anaërobic, and thrive at the temper-

ature of the human body; a temperature of 122°–136.5° F. (50°–58° C.) causes their destruction in ten minutes.

Pseudo-diphtheria Bacillus or Bacillus Xerosis.—From many cases, often showing no lesions, an organism may be obtained that is identical in appearance, manner of culture, growth, etc. with the bacillus diphtheriæ, but inoculation with it causes no lesions. The works of Abbott, Roux, Yersin, and others seem to show that this is an attenuated form of the true bacillus, and varying grades of pathogenicity may be found between the two. The distinction from the pathogenic bacillus can only be made by determining the lack of infection after inoculation.

Site of Infection.—In the human family the seat of election of the bacillus diphtheriæ is usually the faucial mucosa, and less frequently other mucous surfaces and abraded skin. The bacilli do not penetrate the mucosa, and hence do not find their way into the lymphatic or circulatory system, but remain at or very near the site of the local changes.

The Toxins.—Toxins are absorbed from the diseased spots by the lymphatics and blood-vessels, and produce the general phenomena in uncomplicated cases. They have been isolated from artificial cultivations of the microbe, and when inoculated the chief ptomain of the Klebs-Löffler bacillus so modifies the solids and liquids of the body as to render the subject immune (Behring). Another, however, if employed in like manner, produces dangerous and even fatal symptoms (convulsions, paralysis, etc.).

It is certain that the bacillus can maintain an existence for months outside of the body, though its usual habitat is unknown unless it be the organic constituents of the superficial soil. The virulence of its products is modified by many individual conditions, and chief among these is a healthy and intact condition of the mucous membranes, which greatly reduces the susceptibility to the disease.

Associated Microbes.—With the Klebs-Löffler bacillus are frequently found other microbes, especially streptococci and staphylococci. These pass beyond the site of local infection, reaching the internal viscera and other structures, and, as will be seen hereafter, give rise to the serious septic element of the disease. W. Bloch and P. Sommerfeld,¹ in studies on the pathogenicity of the Löffler bacillus, have verified the accepted statement with reference to the germ, their article being a good exposition of the present status of the bacteriology of diphtheria. From a study of 436 cases, the authors state that the Löffler bacillus was never found in culture, but always associated with other bacteria, among which streptococci played the greatest part. The two doctrines concerning the relation of streptococci to septic diphtheria are given, the one being that the streptococci increase the virulence of the diphtheria bacillus and cause sepsis by gaining access to the circulation; the other is that the diphtheria toxin, by its effect on the organism, prepares the way for an invasion by streptococci. The pneumococcus may be found.

Modes of Infection.—When the bacillus leaves the body of the sick it is contained in particles or shreds of the diphtheritic membrane or in the expired air. Infection may then occur (a) *By direct contact* with the shreds of membrane thrown off—*e. g.*, when the latter are ejected by coughing and lodge upon the conjunctivæ or faucial mucosa of bystanders. The deadly poison is sometimes transferred to the physician and

¹ *Arch. f. Kinder.*, Bd. li., Heft 2.

attendants, with resulting infection, from the sucking of tracheotomy tubes. (b) *By inhaling the air* surrounding the patient (contagion). Infection by contagion, however, does not extend beyond a radius of a few feet from the patient. (c) A very leading matter of conveyance of the bacillus from the sick to the healthy is by *fomites*. The contagion adheres tenaciously to a great variety of objects (toys, clothing, library books, letters, slates and drinking-cups in the public schools, etc.), and in this way the germs of diphtheria have been transferred over great distances and have given rise to the disease long after. The latter fact renders it difficult to trace certain cases to previous ones, to which they invariably owe their origin. (d) *Sewer gas, per se*, is to be regarded as non-pathogenic, or at least so far as this affection is concerned (Laws). It may, however, become a carrier of diphtheritic poison. (e) *Domestic animals* may be occasional carriers, especially cats. (f) The disease is kept alive in a community largely by virulent organisms in immune persons ("healthy carriers"). Rarely, "latent carriers," who conceal the bacillus for a time before they show the clinical evidences of diphtheria, may convey the disease.

Our knowledge as to how the infection occurs is incomplete. We know definitely the usual point of local infection in man, and also that a catarrhal mucosa or an open lesion of a mucous surface invites infection. It is not certain, however, that even a slight lesion of the mucous surface is essential to infection. Some writers claim still that the Klebs-Löffler bacillus may enter the blood through the respiratory system and give rise to primary constitutional symptoms, the local manifestations in the throat being secondary. I have met with only a single instance that would lend support to this view.

Predisposing Factors.—(1) *Age*.—This is the most important factor, diphtheria being, in the main, a disease of childhood. Most cases occur between the second and seventh years, while the receptivity diminishes rapidly after the tenth year. Instances have, however, been observed up to the fiftieth or even the sixtieth year. During the first year of life also it is rare. (2) *Sex*.—This is without appreciable influence. (3) *Season*.—Cases are more numerous in winter and spring than at other seasons. (4) *Climate*.—Diphtheria is met with less frequently in tropical than in temperate and cold climates. Humidity favors the propagation of the diphtheria germ, and hence damp cellars also promote the spread of the disease. (5) *Unhygienic Conditions*.—Unfavorable sanitary surroundings tend to lower vitality, thus increasing the susceptibility to the specific virus. Most epidemic outbreaks have held more or less intimate relationship with decomposing organic matter, defective drainage and sewage, cesspools, etc., though it is to be especially remembered that the disease often prevails in sparsely-settled rural districts.

Immunity.—A single attack does not confer perfect immunity. Second and third attacks not infrequently occur in the same individual.

Symptoms.—**Incubation.**—The *duration* of this period is from two to seven or ten days, and in a small percentage of the cases it may be longer. In virulent epidemics and when the disease is produced experimentally the incubation-stage is short—from twelve hours to two or three days. The *prodromal indications* of diphtheria are not strikingly characteristic. They may either be acute in character or very mild; but usually the child will complain of feeling weary and indisposed to

play, of sensations of chilliness, and of pain in the head, back, and limbs. In young children the onset of diphtheria, as in other infections, may be marked by *convulsions*. There is nothing in this early stage of the disease to distinguish it from many of the other affections of children, such as simple pharyngitis or tonsillitis. There may be some fever, not very high—an elevation of one or two degrees at most. The urine contains a small amount of albumin. The child often complains of discomfort in swallowing, and on examination the fauces will be found to be reddened, and in a short time the exudate will be found on the tonsils or soft palate. This is the usual type of **simple tonsillar diphtheria**.

Pharyngeal Diphtheria.—The symptoms are usually *slower of development* than in tonsillitis. The child is sluggish, looks heavy-eyed, languid, and pale for several days. The *fever* may not rise above 101° or 102° F. (38.8° C.). On examining the throat, however, it is found to be swollen and red, and if *lividity* is more pronounced than the swelling, it suggests the true nature of the disease. The *membrane* begins on the tonsils in the form of small patches of yellow exudate, resembling the thick, cheesy plugs of inspissated dead epithelium and secretion which issue from the mouths of the follicles of the tonsils during the course of acute or chronic tonsillitis. Quite early this exudate is easily removable. The membrane spreads from the tonsils to the soft palate and half arches within a few days, and it may also appear on the pharyngeal wall. During this stage the throat may become much swollen and the tonsils greatly enlarged, frequently meeting in the median line. The *glands* immediately beneath the angle of the lower jaw on one or usually both sides become hard, painful, and slightly enlarged; the swelling of these glands is not great in mild forms, although their presence, in association with the foregoing symptoms, is an almost infallible indication of the disease. The child, as a rule, shows grave constitutional symptoms for a few days and albuminuria is present. The *temperature* is not characteristic, as a rule not being high, and the pulse is rapid and weak, being out of proportion to the general indications of the disease. In mild cases the symptoms abate by the end of the first week, and the pseudo-membrane separates, leaving a red, inflamed surface behind. The child is prostrated for a number of weeks, and in about 20 per cent. of all mild cases the toxic effects of the disease may show themselves in the form of a neuritis, with its accompanying paralysis. Simple leukocytosis is present in diphtheria, although this symptom may be absent in mild cases.

Variations in Manifestation.—Diphtheria may exhibit a number of variations as regards the seat of attack and the severity of the poisoning. In some epidemics the Klebs-Löffler bacillus seems to be more active and more numerous, or perhaps more virulent, than in others. The severity of the attack does not seem to depend on the amount of the pseudo-membrane, but rather, according to Rotch, upon three factors: (1) the virulence of the bacteria; (2) the local resistance; and (3) the general resistance. The mucous membrane of any part of the body (lips, tongue, conjunctivæ, vulva, or glans penis) may be the seat of the membranous growth.

Malignant Diphtheria.—The symptoms are severe from the commencement. There are one or at most two days of slight illness, and then alarming symptoms manifest themselves, *cardiac failure* possibly setting in without a specially severe local lesion. *Vomiting* and *high*

fever, resembling the onset of scarlet fever, may initiate the attack; and within a few hours we may find extensive swelling at the angles of the jaws, with a feeling of stony hardness, a very offensive, bloody discharge coming from the nostrils, accompanied with difficulty in opening the mouth. If the *throat* is examined, there will be found extensive swelling of the tonsils, even to meeting, the uvula and soft palate being edematous and covered with much sloughy-looking membrane. The *temperature* in severe cases soon reaches a point between 103° and 104° F. (40° C.), while the *heart-beats* become exceedingly feeble. In a day or two the cellulitis extends, the face becomes edematous, the skin pits all over the face, neck, sternum, and chest-walls. The patient soon becomes drowsy, cyanotic, and occasionally an erythematous rash appears about the face, neck, and chest, while a purpuric rash is not infrequent in malignant cases. Death occurs in such cases within one week from toxemia. Cases of diphtheria septicemia have been recorded in the literature by Mahler¹ and others.

Nasal Diphtheria.—In all severe cases of pharyngeal diphtheria the inflammatory process is likely to extend to the nasal mucous membrane. In some cases the nasal mucous membrane is found to be the first involved; the exudate may spread to the tonsils, involving the back of the soft palate and pharynx as well. In many cases of nasal diphtheria no membrane may be found during life; there may be only a purulent discharge with blood, the presence of which in the nasal passage obstructs breathing, giving rise to a bubbling sound, and rendering sleep troublesome and noisy. Many cases have also been reported of formation of pseudo-membrane in the nose with mild general symptoms (often insignificant), and from which organisms identical with diphtheria bacilli were obtained by culture. Sometimes the cases have recurring mild attacks of pseudo-membranous inflammation of the nose, while the bacilli may be constantly present. It is probable that these cases may give rise to infections of like nature, and even of true diphtheria. In nasal diphtheria the symptoms are quite as severe as in faucial diphtheria, and in cases in which the soft palate and tonsils are also involved the general symptoms, the depression, and also the albuminuria are apt to be well marked. In all cases of coryza with fever we should be guarded as to opinion, especially if an epidemic of diphtheria is prevalent at the time. The diphtheritic inflammation may spread from the nose to the conjunctivæ, with the formation of a false membrane, and much purulent discharge may escape from the eyes, the lids of which may be greatly swollen. In this place it is well to remember that in *measles* we sometimes have a form of membranous exudation occurring on the nasal mucous membrane and as a primary disease—"rhinitis fibrinosa"—which is not always diphtheria. This disorder runs a favorable course, the membrane being less adherent than in diphtheria. Ravenel has collected 77 cases, and in 33 out of 41 cases examined bacteriologically the Klebs-Löffler bacillus was found. Constitutional symptoms were either slight or wanting.

Wound-diphtheria.—The bacillus will not live on normal skin, but when the skin is cut or bruised, as after blistering or an eczematous condition, and when a moist, raw surface is present, this germ freely

¹ *Berliner klinische Wochenschrift*, 1907, xliv., 1499.

flourishes. Granulations also form a favorable soil. The diphtheritic germs may be introduced into the system during an operation, such as an excision of the tonsils, or even a vaginal examination; and in newborn infants the granulating surface left after sloughing of the cord may become the seat of diphtheritic inflammation.

Laryngeal Diphtheria or Membranous Croup.—The exudate may appear first on the mucous membrane of the larynx, and in these cases the mucous membrane of the nose and pharynx may never give evidence of a false membrane. A close inspection of the posterior aspect of the palate and tonsils, however, may reveal a slight primary membranous formation in these situations. In laryngeal cases the first symptom is a *cough* of a *harsh, metallic, ringing character*, and never to be forgotten when once heard. The *temperature* may be slightly above normal, or even, in many cases, normal. The toxic absorption is slight, on account of the locality affected, and the constitutional symptoms are usually mild. The *local symptoms*, however, are very alarming, and result from laryngeal obstruction, there being marked *dyspnea* with retraction of the intercostal and supraclavicular spaces, and later of the epigastrium and lower chest, with an increasing *cyanosis*. The child is soon restless, is forced to sit up to breathe, and for the same reason bends forward with its head thrown back. In these extreme cases unless relief is soon gained the child dies of suffocation. In many instances a slower form of suffocation may result from the extension of the membrane downward to the bronchi.

Complications.—Local complications may be mentioned—*e. g.*, *hemorrhage* from the nose and throat in the more severe ulcerative cases. *Skin-rashes* are not unusual, especially *diffuse erythema*.

Broncho-pneumonia is the most serious pulmonary complication of diphtheria. It is not produced by the Klebs-Löffler bacillus as a rule, but by the streptococcus or pneumococcus. Broncho-pneumonia usually terminates laryngeal cases that have been operated upon.

Albuminuria is a constant symptom (not a complication) of the disease (*vide supra*), and is almost as certain in establishing a diagnosis of true diphtheria as a bacteriologic examination. It is met with in both mild and severe cases, and the greater the amount of albumin the more severe the case. Acute nephritis not infrequently complicates diphtheria; it is usually not accompanied by edema or anasarca. It may set in with suppression of urine.

Dysphagia may, by its constant existence throughout the disease, produce a profound impression on the general nutrition. Involvement of the *conjunctivæ* is a rare but grave complication.

Otitis media occurs frequently, and may be a troublesome complication as well as a sequel. Snow¹ reports a case of diphtheria complicated with Escherich's pseudo-tetanus.

The most frequent *sequelæ* are anemia, chronic naso-pharyngeal catarrh, and peripheral neuritis and its associated paralysis.

Anemia may so prolong convalescence as to expose the child to some intercurrent disorder. The *chronic naso-pharyngeal catarrh* may be marked and offer a favorable ground for new diphtheritic invasion. *Paralyses*—*e. g.*, palatal and cardiac—may appear in the first and second weeks of the disease. Other forms of paralysis occur later. Par-

¹ *Amer. Jour. Med. Sciences*, Dec, 1902.

alysis usually is first seen when the child attempts to swallow, and the food, especially if liquid, is regurgitated through the nose. This is due to a paralysis of the muscles of the soft palate, which also produces a peculiar alteration of the voice. The paralysis may take a general form, such as is seen in multiple neuritis, the lower extremities being affected and the knee-jerk absent. It may extend to the external ocular muscles and cause squint, to the ciliary muscles and cause dimness of vision from unequal accommodation, or to the muscles of the trunk in general, producing widespread paralysis. The child, unable to hold anything, may stagger about as if intoxicated, so much so as to suggest the existence of a cerebral tumor. The disturbance of vision and the absence of the patellar tendon reflex has in adults led to a mistaken diagnosis of *locomotor ataxia*. Loss of taste, deafness, and a disturbance of sensation are not infrequent. Thus, paralysis is to diphtheria what dropsy is to scarlet fever—a proof positive of the disease. To make one step more, in many sudden deaths occurring in early diphtheria, we must recognize *paralysis of the heart* outside of all toxic influence. In these cases there occurs sudden disturbance of the vagus, which may be the seat of degenerative changes in some instances at least. The *prognosis* in post-diphtheritic paralysis after the third week is favorable, while the cardiac, pharyngeal, and diaphragmatic palsies beginning before the third week are serious. Myocardial weakness tends to supervene as a sequel. It is evidenced by the sudden accession of pallor, nausea, sometimes by vomiting, and also by weak heart-sounds and a feeble, broken, irregular pulse, etc., and usually leads to a fatal termination.

Diagnosis.—The diagnoses of a pharyngeal diphtheria is not difficult if an epidemic be prevailing. The false membrane on the fauces and the presence of albumin in the urine give us a practically certain diagnosis. The only unequivocal evidence of the disease, however, is the finding of the Klebs-Löffler bacillus in the membrane.

An immediate recognition of the disease is often possible from a smear-preparation of the exudate from the throat (see Fig. 14), the Klebs-Löffler bacilli being present in sufficient numbers to be readily distinguished by the microscopist. Park, who has had a rare experience with this affection, makes the following statement: "In cases in which the disease is confined to the larynx or bronchi, surprisingly accurate results can be obtained from cultures, and although, in a certain proportion of cases, no diphtheria bacilli will be found in the first, yet they will be abundantly present in later cultures. We believe, therefore, that absolute reliance for a diagnosis cannot be placed upon a single culture from the pharynx in purely laryngeal cases." When a bacteriologic examination cannot be made the practitioner must regard as suspicious all forms of throat affections in children, and carry out measures of isolation and disinfection. In this way alone can serious errors be avoided. Mistakes usually occur in the lighter types, many of which are in reality due to the Klebs-Löffler bacillus (Osler).

Differential Diagnosis.—From *follicular tonsillitis* we differentiate diphtheria by the seat of the membrane, that of the former being *in* the tonsils, while diphtheritic membrane is *over* the tonsils and *over* the soft palate. Moreover, in follicular tonsillitis the fever is high, the onset is sudden, and it is usually associated with gastric disturbance. Albu-

minuria is generally present in diphtheria, while it is present in follicular tonsillitis in exceptional cases only. Moreover, mild cases may not present albuminuria, or fail to show the presence of albumin until later in the disease. The histories of the two cases are quite different. (For differential diagnosis between diphtheria and follicular tonsillitis, see also Table, p. 752.) In many instances of so-called diphtheroid lesions the membrane is formed only by streptococcus pyogenes (*membranous angina*), and these cases are sometimes of an intense grade.

Croupous or membranous angina (a streptococcus infection) may offer some difficulty; yet in this disease there is no tendency to spread to the nasal mucous membrane or to the larynx; there is a diminished glandular enlargement; there is no albumin, and the onset is more sudden.

In *Vincent's angina* there is an absence of the formation on the surface of the mucosa of a thick false membrane, such as occurs in diphtheria. There is a deep and often widespread necrosis of the mucosa of the palate and tonsil. Bacteriologic examination shows the presence of a large number of atypic bacilli, which are often associated with a spirillum. According to H. W. Bruce¹ there is an absence of the diphtheria bacillus.

FIG. 14.—1, A tube of blood-serum; 2, a sterilized cotton swab in test-tube.

Rub the swab gently but freely against the visible exudate, and without laying it down, after withdrawing the cotton plug from the culture-tube, insert it into the latter, and rub that portion which has touched the exudate gently but thoroughly over the surface of the blood-serum without breaking its surface. Now replace the swab in its own tube, plug both tubes, and place them in the box provided by the health officials. This is to be sent to the bacteriologic expert. In laryngeal diphtheria the swab is to be passed far back and rubbed freely against the mucous membrane of the pharynx and tonsils.

Diphtheria frequently is associated with a rash, rendering it difficult to distinguish the condition from *scarlet fever*; but in diphtheria the rash is more truly an erythema, while in scarlet fever it consists of slightly raised points between which there may be an erythematous condition. The rapid pulse of scarlatina is of assistance in the discrimination. The glandular swelling and sloughy condition of the throat, however, closely resemble diphtheria, and a positive diagnosis without a bacteriologic examination is often impossible.

Prognosis.—Formerly diphtheria was at the same time the most prevalent and most fatal of the acute infections, the mortality being 30 to 40 per cent., although variable in different epidemics. The case-mortality from diphtheria has been very materially reduced since the introduction and wide use of antitoxin—certainly over 50 per cent. The remarkable diminution in the death-rate from laryngeal diphtheria has coincided precisely with the use of antitoxin. Of especially unfavorable prognosis are those cases that show large quantities of albumin in the urine, cervical glandular enlargement, excessive nasal discharge, rapid

¹ *Lancet*, July 16, 1904.

extension of the exudate, a necrotic membrane, vomiting, and partial or complete suppression of the urine. A sudden fall of temperature to a subnormal level and an irregular pulse, or bradycardia, are a bad augury. Recovery from a severe attack in which there are extreme depression and much albumin is unusual, especially in a child under six years of age, though recovery takes place frequently in what would be regarded as hopeless cases. The results of Morse's extensive observations are opposed to those of Bouchot and Dulinsay, who claim that the degree of leukocytosis is of prognostic value. The cases of neuritis invariably recover. The child is liable to suffer from the effects of the disease for years after apparent recovery.

The *causes of death*, in their order, are as follows: membranous croup or laryngeal stenosis; septic infection, which may be a slow death; sudden heart-failure—paralysis of the heart; bronchopneumonia, following tracheotomy or occurring during an advanced stage.

Treatment.—**Prophylaxis.**—The best preventive measures against diphtheria are a clean nose and mouth. The slightest appearance of a coryza must be overcome at once by the use of a mild antiseptic wash; all accumulations of crusts, dust, dried blood, etc., should be removed from the nose twice daily, especially in children attending school or during the prevalence of an epidemic. The child should be early taught to employ a small antiseptic gargle as a daily routine, using a weak solution of hydrogen dioxid or listerine. The teeth should be carefully cleaned daily, and all decaying teeth should be filled or removed. Since domestic animals, especially cats and dogs, may communicate the disease, they should be excluded from the sick room.

All cases of sore throat should be examined for the Klebs-Löffler bacillus, and, if it is found, the individual should be isolated; and all cases of diphtheria should be kept isolated until cultures taken from the throat or nose fail to indicate the presence of the specific germ. This is especially true in schools and asylums. Moreover, the throats of all persons exposed to this disease, and of those caring for diphtheritic patients, should be frequently examined for the Klebs-Löffler bacillus, and if it be found, the person should receive immunizing doses of antitoxin. Bacteriologic examination of the throats of school-children is of the greatest aid in controlling epidemics. The fact that the Klebs-Löffler bacilli when found in healthy throats may not be active is no argument against isolation and antitoxin injections, because if the same germs were to find a broken or catarrhal membrane they would rapidly develop.

An unrecognized feature in the prophylactic treatment of the disease is seen in the uncertain period of convalescence. It frequently happens that long after all membrane has disappeared active bacilli may still cling to the throat. The persistence of the bacilli may be accounted for at times by assuming that the accessory sinuses of the nose may be involved. This condition may also continue for from two to six months, and even longer in deeply fissured tonsils; and the disease may be communicated by such throats in the act of kissing young children or adults with sensitive throats or with a broken buccal mucous membrane. For this reason the indiscriminate kissing of young children on the lips should be interdicted by the physician.

Insufficient attention to isolation and disinfection of the milder cases explains the occurrence of many house-epidemics. The physician must, during his visits, wear a surgeon's apron or linen duster which has been steeped in a mercuric chlorid solution and allowed to dry. His hands and face should be washed in a similar solution on leaving the room.

Treatment of the Attack.—The treatment falls naturally under several departments: (a) the hygienic measures to limit the diffusion of the disease; (b) the local management of the throat to destroy early the toxic germs; (c) medication to antagonize the effect of the toxins, and eventually to overcome the complications and sequelæ.

(a) **Hygienic Treatment.**—The patient should be in a room well exposed to sunlight and fresh air, and superfluous furniture and hangings should be promptly removed. No stationary washstand should be allowed in the room, and Goodhart well says that many cases seem to have their origin in the proximity to foul-smelling drains. Even in mild cases the patient should be kept in bed throughout the attack. White and Smith, from a study of the heart complications in 946 cases of diphtheria, believe that the presence of murmurs and a slight degree of irregularity are no contraindications to getting out of bed at the end of two weeks, if the first sound is strong and the heart is not dilated. Patients who have been severely ill, or ill several days without treatment, should not be allowed out of bed before five weeks. The general comfort of the patient is enhanced by two daily sponge-baths of tepid salt-water or of alcohol and water.

Feeding.—Nursing infants may be fed on breast-milk obtained by a breast-pump, but should not be placed at the mother's breast (Holt). The feedings should be regular, yet lighter in quality and quantity than in health, remembering the fact that gastric disturbance is closely associated with diphtheria. The rule must be to pay every possible attention to the feeding. Milk in some form being our main dependence, it should usually be diluted, and for young children partially if not wholly peptonized. The greatest difficulty comes in the latter part of the disease, when the child is septic and most likely has a strong objection to being disturbed. At this time vomiting is most easily provoked and swallowing is rendered very difficult on account of the swelling and pain. We must not neglect the feeding even if it does cause discomfort, and here forced feeding by means of gavage is most valuable. Gavage is likely to be more successful with children under three years than rectal alimentation. In older children who object to the tube through the mouth, it may be passed through the nose with little difficulty, and gavage by this route, even in intubated cases, will be extremely satisfactory. Concentrated broths, meat-juice, and even milk-punch or raw eggs, may be given in this way.

(b) **Medicinal.**—*Alcohol* no longer holds a debatable ground in the treatment of diphtheria; it is the most powerful drug in our possession to offset the ravages of the disease on the nervous centers and for the control of the circulation. Stimulation should be commenced as soon as there is a reasonable certainty as to the correctness of the diagnosis, and by commencing early with whiskey or brandy we may prevent the depressing effects of the poison of diphtheria as seen in the pulse and general condition of the child. The indications for the free use of alcohol are marked prostration, feeble pulse, and a weak first sound of the heart. The

quantity must be adjusted to the age and gastric condition of the child, and usually one ounce (32.0) of good whiskey or brandy, well diluted, in twenty-four hours is sufficient for a child four years old. In very bad cases five or six times this quantity may be given, the only limit being the tolerance of the stomach. The stimulants should be mingled with the food, as the child may rebel against taking both food and stimulants.

Strychnin stands next to alcohol in importance in the treatment of diphtheria, and usually it is given in too small doses. For a child four years old gr. $\frac{1}{30}$ (0.0021) may be given every six to eight hours, and may be administered in little tablets by the mouth or hypodermically.

Digitalis does not hold an important place in the heart-weakness of diphtheria, and yet it is strongly indicated on theoretic grounds. Clinically, it has been found to have an unfavorable action on the stomach before its good influence can be had on the heart itself. The same may be said of camphor and ammonium carbonate. The aromatic spirits of ammonia is valuable for rapid effects in syncopal attacks. In cases of threatened heart-paralysis occurring late in the disease Holt has found nothing so valuable as morphin employed hypodermically, the drug being given in full doses and repeated every two hours, keeping the child under its influence for some days. In cases of diphtheria in which a murmur and slight arrhythmia develop, efforts at treatment should be concentrated on the general condition.

Internal medication should be minimized. Symptoms, as vomiting or diarrhea, are to be met with sufficient therapy only for their control.

(c) **Local Treatment.**—For the direct attack upon the membrane in the throat nearly all the remedies of the Pharmacopeia have been used. Gargling, swabbing, painting, spraying, and washing the throat, all have their advocates. Since the acceptance of the antitoxin treatment medical opinion has suffered a decided change as to the importance of local measures. The very best local application for pharyngeal or nasal diphtheria consists of hydrogen dioxid, diluted one-sixth, and used both as a gargle and spray as most convenient; this is usually sufficient in the early stage. Norikove¹ advises for infants who cannot use a gargle the administration of peroxid internally by the following formula: hydrogen dioxid, 5 to 7 c.c.; distilled water, 85 c.c.; syrupus simplex, 15 c.c. I have found a solution of mercuric chlorid, 1 : 1000, with an equal part of hydrogen dioxid, used as a spray, an excellent disinfectant and detergent. The tincture of iron and glycerin (one part of the former to two parts of the latter) is a valuable local remedy; it should be applied by means of a swab. The object of local treatment is a more thorough cleanliness—the prevention of systemic absorption of the ptomaines. To avoid new lesions in making applications, the spray alone should be used, and for the nose boric-acid solutions or hydrogen dioxid, 1 : 10, will be most serviceable. Fackenheim's experience with a local spray of pyocyanus convinced him that it is a valuable adjuvant to the serum treatment; it hastens the disappearance of the throat lesions and improves the general health. In this work the utmost tact and kindness must be maintained, for it is truly pitiable to force a struggling child. Warm, weak solutions, most thoroughly applied by means of the fountain-

¹ *La Médecine*, Oct. 8, 1902.

syringe, often have a better effect than the more frequent use of the hand-syringe or spray in cases of nasal diphtheria.

In laryngeal diphtheria the child should inhale an atmosphere laden with the vapor of slaking lime, or, whenever practicable, an atmosphere saturated with Löffler's solution (menthol 10 grams, dissolved in sufficient toluol to make 36 c.c., liq. ferri sesquichlorid, 4 c.c., absolute alcohol, 60 c.c.). J. Cordin warmly recommends mercurial fumigation for the relief of laryngeal stenosis. The development of the signs of actual stenosis, as shown by stridulous breathing, cyanosis, etc., furnishes an indication for either intubation or tracheotomy. According to my observations, the results of intubation have been quite favorable, and I would strongly recommend a trial of this procedure before resorting

FIG. 15.—Temperature-chart of a case of diphtheria.

to tracheotomy (see temperature-chart, Fig. 15). To obviate the necessity for reintubation, vapor inhalations have been successful in my hands.

(d) **External Applications.**—External applications to the throat have no effect on the course of the disease. They are useful, however, in relieving the pain and the swelling in the lymph-glands. Careful massage of the neck with camphorated oil, as hot as the skin will tolerate, is very soothing; and soap liniment may be used in the same way, or, if much pain exists, chloroform liniment may be substituted. Poulticing for the relief of pain is not desirable, as it seems to favor suppuration. In older children the ice-collar has been used with good effect, and it soon brings grateful relief from the tension and subdues inflammation. All manipulations about the child, however, should be carried on as gently as possible.

Serum-therapy; the Antitoxin Treatment.—This has now passed beyond the stage of uncertainty and experimentation, and must be regarded as one of the most positive advances made in practical medicine. The general average mortality of diphtheria has been reduced by means of the antitoxin treatment to about 15 per cent., and the greatest decrease

has been shown to have occurred in children under six years of age. No physician should be guilty of failure to employ the serum in any case of diphtheria. The studies of Behring, Roux, Kitasato, and others have demonstrated that the use of the blood-serum of the lower animals, artificially rendered immune against diphtheria, has a powerful healing influence upon diphtheria that has been contagiously or spontaneously acquired by man. These experiments were first published in December, 1890. The principle was first shown to be true of tetanus, and, late in 1892, Behring further showed that the blood of an immunized animal had the power both of protecting and of curing susceptible animals which had been inoculated either with the toxins or the bacilli of diphtheria. In preparing the blood-serum it is very desirable, of course, to have a uniform strength or standard. One-tenth of one cubic centimeter of what Behring calls his normal serum will counteract ten times the minimum of diphtheria poison, fatal for a guinea-pig weighing three hundred grams. One cubic centimeter of this normal serum he calls an antitoxin unit. The serum prepared by his method is labelled in three strengths: No. I. is sixty times the strength of the normal serum; No. II. is one hundred times as strong; No. III. is one hundred and forty times as strong.

Dosage.—To a child of two years or over not less than 2000 to 4000 units should be administered at the first dose; hence solution No. I. is rarely employed at the present day. Should a favorable result not be attained, then, on the following day, a similar dose should be repeated, and a third dose if necessary. Massive doses should be employed at the outset in severe cases, in laryngeal diphtheria, and in advanced cases. The sites to be selected for injection are various. In very young children either the buttock or thigh is to be preferred, while in older children the flanks or subscapular spaces may be chosen as well. The injections should be made deeply into the subcutaneous cellular tissue, and the swelling which results should not be rubbed. It is to be emphasized that the best results are obtained from early injections. In laryngeal cases intubation should be combined with the serum treatment in suitable cases. The use of antitoxin in this disease has greatly diminished the proportion of cases in which the usual complications occurred previously.

In fortunate cases the influence of the serum soon becomes apparent. Within twenty-four hours the faucial swelling diminishes, the membrane exfoliates, the temperature falls, the pulse becomes slower and stronger, and the general condition of the patient quickly improves. In cases of moderate severity and when injections are employed early the improvement in the throat and the constitutional symptoms is very decided; and the earlier the case comes under treatment the better are the results. There are, however, some cases of great severity in which the antitoxin has been used early, yet has not shown any benefit. Kronig¹ has found that incising the hard, swollen process enhances the efficiency of the diphtheria antitoxin.

A danger in serum-therapy may be the development of local abscesses, which, if full antiseptic precautions be taken, must be rare indeed. I have escaped them altogether. Certain skin eruptions have been observed after injections, mostly urticarial, though sometimes scarlatiniform. The latter form has given rise to apprehensions of scarlatina. Widerhofer had one case which was isolated as measles, but never developed any

¹ *Jour. of the Amer. Med. Assoc.*, August 8, 1908.

symptoms other than the suggestive eruption. Rarely, joint-pains and swellings, with general prostration, supervene. Two fatal cases have been reported—one¹ that of a healthy boy five years old, the result of an injection of Behring's fresh serum as a preventive, dying within five minutes; the other occurred in Berlin.²

For establishing immunity in subjects exposed to infection the injection of 60 units (1 cubic centimeter of the No. I. serum) affords protection. In order to arrest the development of the disease during the period of incubation 100 units (1 cubic centimeter of No. II. serum) is probably sufficient. Rolleston urges rest in bed from three weeks after a mild angina to seven or eight weeks after a severe attack—as a prophylaxis against palsies. Adrenalin and strychnin have their advocates for the same purpose. Finally, for the serious circulatory disturbances which arise either during or after diphtheria, absolute rest and general management accomplish more than drugs.

SEPTICEMIA.

Definition.—Septicemia is a systemic infection due to a microbic invasion of the blood and tissues, with or without a detectable seat of infection. Sappremia is a toxemia of saprophytic origin (poisoning with chemical products), while *septic* intoxication is an affection due to the absorption of poisons from foci of suppuration. Mixed infections are common, hence it is clinically impossible to differentiate cases of pure sappremia, septic intoxication, and septicemia in most instances.

Pathology.—After death the body putrefies early. The macroscopic changes in the viscera are sometimes few and often wanting. The muscles present a brownish color-tint. The pia mater is generally congested, and, together with the nerve-centers may be the seat of ecchymoses. The blood is dark ("tar-like"); its coagulability is diminished and, microscopically, it shows an abundance of micrococci and bacilli in many cases. The organisms, however, are not so constantly found in the circulating blood as in the septicemia of mice or rabbits. The spleen is somewhat softened and its lymphoid elements more distinct, and almost invariably ecchymoses are found in the serous membranes.

In protracted septicemia more marked alterations exist, and among them may be briefly enumerated the following: endocarditis (rarely ulcerative); gastro-intestinal catarrh (of the duodenum and rectum in particular) with punctiform extravasations; enlargement of the lymphatics and spleen, with softening of the latter; cloudy swelling of the liver (rarely the so-called emphysema of the organ due to putrefaction); edema and catarrhal inflammation of the uriniferous tubules; congestion, sometimes associated with edema of the lungs; and inflammation of the pleura, pericardium, and peritoneum, with ecchymoses.

Microscopically, the internal organs show numerous small foci of inflammation, some of which may be the seat of "coagulation-necrosis." Bacteria are found in abundance in various situations, such as the exudations, the capillaries of the inflammatory foci, and renal glomeruli.

Etiology.—**Bacteriology.**—Septicemia may be due to micrococci,

¹ *Jour. of the Amer. Med. Assoc.*, April 4, 1896.

² *Med. News*, April 18, 1896.

which Koch has shown to be considerably smaller than pus-cocci, though no one form of bacterium has been found constantly present to the exclusion of all others. Besser, as the result of careful experiments, concludes that septicemia is caused solely by streptococci, while Rosenbach and others have found both staphylococci and streptococci. In typhoid fever, pneumonia, gonorrhea, puerperal fever, and the like septicemia may be due to the organism causing the primary lesion. For example, Rosenow found the pneumococcus in 77 of 83 cases of pneumonia in which blood cultures were made. Doubtless in many instances of human septicemia the clinical manifestations are due partly to bacterial poisoning and partly to septic intoxication with the poisons (ptomains) developed by the organisms, and the ptomains probably kill the patient before the bacteria can propagate themselves throughout the system. Laboratory experiments teach us that in the lower animals septicemia can be produced both by chemical poisons and by bacterial infection, and these two types are observed in human beings. With reference to the bacterial form, Warren¹ states: "Whether this process is caused solely by the multiplication of bacteria, or is dependent in part upon the liberation of intensely powerful poisons, or is due to some ferment-like substance capable of reproducing itself, like the poison of the serpent, as are diphtheria and tetanus, much more extensive studies upon the human subject will be necessary to enable us to say."

Modes of Infection and Introduction of the Poison into the System.—(1) **Wounds**, either surgical or the result of injury, with which we have nothing further to do in this work.

(2) **Through the uterus**, following labor, miscarriage, or abortion. Generally in these cases there are accompanying local changes, but in a few the poison appears to pass the unguarded portals of the organ, while the latter exhibits nothing abnormal.

(3) The cases in which the poison gains entrance into the body without obvious wounds or raw surfaces are relatively more common. When the skin is quite natural, septic infection or intoxication cannot occur, but the slightest abrasion or cut, bed-sore, etc. may serve as a gate of admission. These slight lesions "may be almost completely healed by the time the severe symptoms of the disease are developed" (Strümpell).

(4) **Mucous membranes** often admit the virus, being less protective in nature than the skin. The numerous bacteria—benign and pathogenic—that are constantly present in the intestinal canal may also find in local lesions (as in typhoid fever, dysentery, etc.), or catarrhal inflammation even, points of lodgement and cause a systemic infection. To this category belongs that form of septic infection which follows gonorrhea. The so-called cases of "spontaneous septicemia" are also usually occasioned by absorption from the mucous surfaces.

Rheumatic or septic manifestations often follow attacks of *tonsillitis*, and it is probable that the tonsils are more frequently points of entrance for the organism than has hitherto been supposed (Wade, Banatyne).

(5) "**Sepsis Intestinalis.**"—This special form of poisoning is caused by canned meats, ice cream, sausages, and cheese. Vaughan, to whom

¹ *Surgical Pathology and Therapeutics*, p. 340.

we are indebted for the first description of "sepsis intestinalis," found in cheese a ptomain which he named *tyrotoxinon*, and which he regarded as the active agent in this group of poisoning cases. The symptoms are due, according to his statement, to poisoning by chemical substances, being instances of *sapremia*; but it may yet be found that the intestinal micro-organisms play a more or less prominent part in the process.

(6) Ogston¹ recognizes as one of the mildest forms of *sapremia* the sickness and nausea produced by a bad smell, which, he claims, is but a ptomain of putridity that may, under certain contingencies, produce serious symptoms. On the other hand, persons who are habitually exposed to bad odors (workers in sewers, in the dissecting-room, etc.) may acquire a considerable degree of immunity against poisoning of this sort. The fever in these cases corresponds in severity to the dose of the poison.

(7) **Septicemia** may be associated with or follow osteomyelitis.

Clinical History.—(1) **Symptoms of Sapremia.**—The fact that this form may occur without bacterial infection, either local or general, must be emphasized, but more frequently there will be either local infection or putrefactive changes with the production of a grave general condition due to the absorption of the poisonous chemical products. In certain other acute infectious diseases (diphtheria, tetanus, typhoid fever, erysipelas, etc.) the general symptoms are similarly engendered. Perhaps the most typical examples of *sapremia* seen by the physician are those due to *tyrotoxinon* and the unaccustomed inhalation of foul odors. At the beginning a chill may occur, but this is more generally wanting. In "*sepsis intestinalis*" marked *local symptoms* may initiate the attack, as nausea, vomiting, colicky pains, diarrhea, etc., and in all forms there is *fever*, the temperature often rising rapidly to 101° or 103° F. (38.3°–39.4° C.) and sometimes higher. *Prostration* and *anemia*, particularly the latter, may be prominent symptoms. *Microscopic examination* of the blood shows leukocytosis, and always a marked reduction in the number of red corpuscles. The hemoglobin, too, may be reduced.

Sapremia following childbirth is a most typical sub-variety, and, apart from the special history, the symptoms are much the same as those detailed above. It is the form most amenable to treatment, the removal of the cause being followed by a rapid disappearance of all symptoms.

(2) **Symptoms of True Septicemia.**—There is an *incubation*-period which is of variable duration, though usually averaging several days. The *onset* is more gradual than in the previous variety, although often marked by a *chill*. Accession of *fever* following surgical procedures, with headache, anorexia, prostration, sometimes vomiting and diarrhea, and especially dulness occasionally amounting to mild stupor, announce the affection: these symptoms should also excite suspicion in the absence of obvious causal factors. They become intensified, and now the attack may closely simulate certain other infectious diseases (typhoid fever, acute miliary tuberculosis, ulcerative endocarditis, etc.), the clinical picture as outlined presenting nothing characteristic. There are, however, more or less distinctive features, which will be considered seriatim.

(a) **The Fever.**—This is usually of the *continued* type, and tends to

¹ Warren, *loc. cit.*, p. 342.

increase in degree, fatal cases often terminating in hyperpyrexia. At the beginning the temperature may rise quite rapidly, and in some cases it may even be subnormal. Deep morning remissions may be observed, and the initial chill may be repeated.

(b) **The Circulatory System.**—The pulse is frequent, and near the end becomes very weak. In subacute cases characteristic lesions (endocarditis in particular) may develop, but are difficult of recognition, since they do not, as a rule, give rise to audible murmurs or other physical signs. In other instances soft murmurs may be heard, but it is indeed hard to discriminate these from functional sounds. Moderate leukocytosis (principally of polymorphonuclear variety) is observed, and the presence of micrococci in the blood during life has been demonstrated. A more or less severe secondary anemia is present. In toxic states associated with suppuration, *iodophilia* occurs (Cabot).

(c) **Gastro-intestinal System.**—The spleen may become perceptibly enlarged and gastro-enteritis is usually present, either in an acute form with vomiting and frequent serous discharges or, more often, merely with a diarrhea of moderate intensity (septic diarrhea).

(d) **Cutaneous Symptoms.**—Punctiform hemorrhages into the skin are of prime importance in the diagnosis. Occasionally more extensive ecchymoses appear, scarlatinal eruptions also showing themselves, but these are less characteristic. Among rare appearances, herpes, roseola, edematous inflammations, and faint jaundice may be observed.

(e) **Renal Symptoms.**—The lesions constitute the so-called "septic nephritis," the urine often containing a fair amount of albumin, epithelium, tube-casts, and red and white corpuscles.

Diagnosis.—(a) **Sapremia** can be distinguished by the history, the immediate appearance of the symptoms, their character, and by the prompt effect of the removal of the cause. The diagnosis requires a careful search for etiologic factors, though without the latter we can sometimes arrive at a correct conclusion by a process of exclusion.

(b) **True Septicemia.**—Here the existence of an incubation period, the continued fever, mental apathy, faint jaundice, splenic enlargement, and the characteristics of septic nephritis, all combine to form a well-defined group of phenomena. A careful blood-examination should be made for micrococci, etc., and cultures should be undertaken in spontaneous septicemia and associated forms (*e. g.* septicopyemia). The surgeon should look to the condition of the wound if one is present.

Course and Prognosis.—The course may be brief, virulent attacks sometimes terminating fatally within forty-eight hours, this being especially true of sapremia when the dose of the poison is large. The gravity of the case in the latter form is in direct proportion to the amount of virus in the system, the outlook being good when the cause is removable, in true septicemia, however, the progression tending steadily to the end. The mildest types may rarely terminate favorably, but the effects are not dependent upon the dose, and the minutest quantity may lead to specific results in their fullest intensity. Septicemia of chronic course is somewhat milder.

Treatment.—Of first importance is the removal of the cause, and small wounds should be excised and the parts freely cauterized. The physician must support the patient's strength by a suitable dietary and by the judicious use of cardiac stimulants; the former should consist

mainly of liquids (milk, egg-white, meat-juice), and the latter of alcohols, together with strychnin and ammonia. Of medicines, internal antiseptics (mercuric chlorid, creasote, etc.) richly deserve a trial. The fever calls for hydrotherapy. Quinine in large doses (gr. x every four hours) should be given, if well tolerated by the patient. To meet the renal conditions the free use of water, together with the least irritating of the diuretics, is to be advised. A powerful agency in eliminating the microörganisms and their toxic products is found in normal salt solution, which may be administered by hypodermoclysis ("washing the blood"). Not less than from one to several pints of this fluid are to be used daily. In the inoperable cases antistreptococcus serum, although of uncertain value, should be employed. If the blood-pressure is persistently low, adrenalin is valuable when *slowly* administered intravenously in the proportion of five minims of the 1:1000 solution to a pint of warm saline solution (Sajous). At first 1000 units of Marmorek's serum should be injected daily, later at longer intervals. Pearce states that polyvalent sera appear to give most favorable results.

PYEMIA.

Definition.—A disease of the blood invariably associated with secondary abscesses, and due to an absorption of pyogenic organisms.

Pathology.—The cadaver does not undergo putrefaction as early as in septicemia. Briefly considered, the pathologic lesions that fall within the physician's province arrange themselves under the following heads:

(1) **Thrombosis and Embolism.**—At first the veins leading to and from the seat of the local changes from which pyemia arises contain thrombi which may soften into a puriform material. Thrombi are also found in the lungs (a circulating embolus first finding lodgment in the pulmonary artery or its branches), liver, kidneys, spleen, and the cortical substance of the brain. *Fresh emboli* may be formed in the circulating blood. Suppurative phlebitis is almost constantly present.

(2) **Abscesses.**—These so-called metastatic abscesses are set up by septic emboli or result from the thrombi (chiefly pulmonary and portal), and are found in the lungs, liver, spleen, and kidneys. They are not large, but may coalesce and form cavities of the size of an apple. An original focus of suppuration may be the bronchial glands. The kidneys are the chief organs of elimination in this disease, and hence it happens that numerous clumps of micrococci (*infarctions*), producing miliary abscesses, are frequently seen in the regions of the Malpighian bodies. There are many other, though rarer, seats of abscesses, as the muscles, submucous and subcutaneous tissues, bones, the parotid gland, ovaries, and testicles.

(3) **Lesions of the Skin and of Mucous and Serous Membranes.**—At the post-mortem examination hemorrhagic extravasations and pustules are often visible in the skin. The mucous membrane of the alimentary tract is rarely affected, differing in this point from septicemia, though occasionally ulcers may be noted, and most commonly in the stomach near the pyloric orifice (in puerperal cases) and in the large bowel. Probably they are always secondary to the submucous miliary abscesses. The

serous membranes (pleura, pericardium, meninges of the brain, synovial membranes) may be the seat of purulent inflammation and of hemorrhagic extravasations.

(4) **Cardiac Lesions.**—Ulcerative endocarditis forms the chief morbid lesion (*vide* Ulcerative Endocarditis). Myocardial foci of suppuration may be present.

Etiology.—**Bacteriology.**—Experimental investigations have shown conclusively that the organisms usually responsible for this condition are the staphylococcus and the streptococcus. Whether the former or the latter be the agent of infection in the given case depends chiefly upon the condition of the tissues at the starting-point, especially with reference to the character of the local defensive processes; also, though to a lesser extent, the degree of virulence of the micrococci.

Other important pus-producing organisms are the gonococcus, pneumococcus, Friedländer's bacillus, bacillus pyocyaneus, bacterium coli communis, and micrococcus tetragenus. Pyemia may be caused by any wound or inflammation in which the pyogenic organisms are present.

Paths of Infection of the Body.—(a) Almost always the entrance is by the *blood-vessels*, the special varieties of bacteria that cause pyemia reaching the veins and producing thrombo-phlebitis. Less frequently they reach the arteries and produce thrombo-arteritis. From the former condition emboli may be disseminated throughout the system, while from the latter the emboli are arrested in the neighboring capillaries to which the tributaries of the vessel lead. Bacteria independently of emboli may be found wandering in the blood-stream.

(b) The *lymphatic system*, but here the bacteria meet with greater forces opposing their attempts to spread than in the blood-vessels, and hence it is a much rarer mode of propagation.

(c) In *spontaneous pyemia*, in which there is no wound to act as an infection atrium, we must presuppose the existence of either a trivial lesion, as in "spontaneous septicemia," or an area of lessened resistance. The latter may be produced by inflammation, by a contusion, and in other ways, and all that seems necessary is a lowering of the tone of the general system (Warren). I am certain that ulcerative endocarditis is not frequently the starting point, but is usually secondary to foci of inflammation elsewhere. The appendix is often the primary or original focus in this category of cases, micrococci localizing themselves here in consequence of a preceding disturbance of the circulation or catarrhal inflammation. I recollect one case in which no original abscess was found at the post-mortem.

Predisposing Causes.—(a) *Epidemic Influence.*—It has been proved by abundant experience that certain seasons are characterized by epidemic outbreaks of the disease.

(b) Cases have sometimes been noticeably more frequent in the early months of the year (February and March) than in other seasons.

(c) *Age and Sex.*—Males are more frequently affected than females, and most cases occur about the middle period of life or at the time of greatest danger from traumatism.

Clinical History.—**Incubation.**—The disease sets in within the first week after the reception of the wound or operation. The wound looks unhealthy, and phlebitis of the efferent veins is noted.

A most conspicuous symptom, and usually the first, is the *chill*: it may, however, be preceded for a variable time by *fever* of a continued or intermittent type. The fever of pyemia is of the suppurative type. Profound *prostration* develops early; the *skin* presents an icteroid appearance; and gastro-intestinal symptoms may appear, but are not prominent. The signs of abscess of the lung, liver, and other organs may develop in some cases, while in others the whole clinical picture is colored by the ill-defined characters of ulcerative endocarditis.

(a) **The Chill.**—This may be mild, though oftener it is quite severe. It is repeated throughout the course of the disease at somewhat irregular intervals, and rarely it may recur several times on the same day. Chills are most apt to occur during the daytime.

(b) **The Fever.**—A rapid rise of *temperature* accompanies the *chill*. The fever-curve is of the irregularly intermittent or profoundly remittent type, with intervening period, showing slight or marked variations, and as decided deviations may occur within a short space of time, a two-hour record should be kept. The temperature rarely falls to the normal level; it may do so, however, and remain there for one or two days. To explain the peculiarities of the curve in this disease we need only recall the great variety of pathologic processes before noted. With the sharp fall of temperature *sweating* occurs and leaves the patient more or less exhausted, though only temporarily so as a rule.

(c) **Respiratory System.**—Symptoms referable to the organs of respiration appear early. The pulmonary abscesses are usually latent, but may give rise to dyspnea, cough, and occasionally a purulent expectoration. *Pain* is present if they are superficially located, and under such circumstances the physical signs of cavity or of pleural effusion may be noted. The signs of *pneumonia* at one or both bases may also develop, the expectoration now becoming rusty.

(d) **Splenic and Hepatic Symptoms.**—The foci of suppuration in the liver are difficult of recognition unless they become large as the result of coalescence and are superficially located (see article Hepatic Abscess). Splenic infarction may also be safely diagnosed if there are pain and great tenderness (due to localized peritonitis) in the left hypochondrium, with progressive enlargement of the organ. In one case I detected distinctly crepitant sounds over the site of the spleen during life.

(e) **Cardio-vascular Symptoms.**—The *pulse* at first is accelerated, but moderately full and regular; later it becomes feeble, rapid (running), or even uncountable. Frequently cases in which ulcerative endocarditis develops are apparently of spontaneous origin. (*Vide* Endocarditis in the section on Diseases of the Heart.) Among the blood-appearances during life are *leukocytosis* and a rather marked reduction in the red corpuscles, with moderate poikilocytosis. Iodophilia is a frequent finding. Nucleated erythrocytes may be present. The blood-plaques are increased. Purulent pericarditis may occur.

(f) **Cutaneous Symptoms.**—The most prominent is a mild yet decided grade of *jaundice*, that is hepatogenous (?) in nature. Sweating has already been alluded to as a symptom, both during and after the febrile paroxysms. The skin finally shrinks from emaciation. *Skin-eruptions* are common, particularly erythema, purpura, pustules, pallor, and the general surface is often decidedly *hyperesthetic*.

(g) **Genito-urinary Symptoms.**—The urine is concentrated and urates are copiously deposited. There is *albuminuria*, which may be due to the pathologic changes or may be ascribable to the fever. The microscope discloses the presence of tube-casts, micrococci, pus- and (more rarely) blood-corpuscles. Peptone has been found in the urine.

(h) **Nervous Symptoms.**—The mind generally remains unclouded until an advanced stage is reached; then delirium sets in, and is followed by a terminal coma. Metastatic purulent meningitis, with its usual symptoms (hemiplegia, strabismus, ptosis, deafness, etc.), may appear.

(i) Symptoms may be presented by the joints and bones. Metastatic arthritis, usually suppurative, is a not unusual concomitant, and in some cases it is combined with similar involvement of the long bones. An acute osteomyelitis may be the only ascertainable source of the pyemia.

Septico-pyemia.—By this term is meant the combined presence of suppuration and a general intoxication (septicemia). The symptoms of pyemia (recurrent chills, copious sweats, metastatic abscesses, and early nervous symptoms dominate the scene in the majority of the cases. Some of these instances pursue a comparatively mild, chronic course.

Differential Diagnosis.—The disease is often confounded with malarial intermittent fever (*vide* p. 356), *acute miliary tuberculosis*, *malignant endocarditis*, and, more rarely, *typhoid fever*. Malignant endocarditis, the secondary condition, is, however, pyemic in nature. Typhoid fever is distinguishable by the Widal reaction, characteristic eruption, and course. A few points of contrast, by means of which *septicemia* and *pyemia* may be differentiated, are tabulated below:

| PYEMIA. | SEPTICEMIA. |
|--|--|
| Always associated with suppuration. | Suppuration may be absent, but there may be a sloughing wound. |
| Multiple chills. | A single chill, as a rule. |
| Irregularly intermittent fever-curve. | Continued type of curve. |
| Profuse sweats accompanying febrile attacks. | Absent. |
| Rapid emaciation and profound prostration. | Less marked. |
| Sensorium is rarely affected. | Sensorium seldom normal. |
| Hyperesthesia. | Absent. |
| Slight jaundice. | Less marked (very faint). |
| Metastatic abscesses. | Absent. |

Prognosis.—Pyemia may kill after an illness lasting but a few days. On the other hand, it may become more or less protracted, so that a chronic form has been distinguished. In this variety the symptoms are milder in character, and recovery may rarely ensue.

Treatment.—So far as the physician's province extends, the treatment is identical with that of septicemia. For the sweating the best agents are aromatic sulphuric acid and atropin; the latter may be given with agaricin (atropin, gr. $\frac{1}{120}$ —0.0005; agaricin, gr. $\frac{1}{8}$ to $\frac{1}{4}$ —0.008 to 0.016), at bedtime. Prompt surgical interference must be resorted to not only with a view to asepsis of the primary wound, but also to evacuating the primary and all secondary foci of suppuration. Recently puerperal pyemia has been successfully treated in this way. The use of antistreptococcic serum has led to immediate improvement. The employment of normal saline solution by the method of hypodermoclysis aids in eliminating the peccant material.

ACUTE ARTICULAR RHEUMATISM.

(Rheumatic Fever.)

Definition.—An acute febrile disease, probably due to a diplococcus. It would seem to be a general infection, the commonest seat of the principal lesion being the joints, “but also involving the heart, both endocardium, pericardium, and muscle, occasionally the meninges and other structures” (Webster). Hueter first advanced the germ-theory to account for the disease, and, although the specific causal agent has not as yet been discovered, this view is the only one that offers a satisfactory explanation for the production of the lesions, the acute onset, the clinical course, and the complications of the disease. The frequent involvement of the joints in many diseases belonging to the acute infections may properly be regarded as supporting this theory. Strümpel points out the fact that in Leipsic, where articular rheumatism is one of the most frequent of acute diseases, at certain times there are only a few cases, while at others there is a striking increase in the number.

Pathology.—The disease does not show peculiar lesions, and, although the joints are the chief seats of invasion, still in many instances and even in aggravated cases, the changes presented are slight or altogether wanting. Usually the synovial membranes of the affected joints are injected and swollen, and their surfaces may be more or less coated with fibrin. The effusion, which in a majority of instances has been found sterile, is mainly serous, but contains fibrin and often leukocytes, and occupies the joints. A similar exudate infiltrates the periarticular tissues. The tendinous sheaths may also be inflamed; the cartilages in protracted cases may become eroded; and rarely a purulent exudate may be seen.

Fatal cases, except when death is due to hyperpyrexia, usually show the changes peculiar to endocarditis, pericarditis, or myocarditis, and less frequently those of pneumonia, meningitis, or pleuritis. The fibrin-factors of the blood are augmented.

Etiology.—**Bacteriology.**—Guttman, Collin, and Sahli have found the staphylococcus in the articular exudate of patients suffering from complicated or recurrent cases of acute articular rheumatism, and Sahli is inclined to include the disease in the group caused by this organism. Netter, however, has found the streptococcus, and Lang a peculiar bacillus. Singer has examined 92 cases bacteriologically and discovered staphylococci or streptococci in the majority of these cases, and also post-mortem; they probably complicate acute rheumatism. Pierre Achalmé¹ has described an organism which he found in the blood (*Thirolaix Achalmii*) of cases of rheumatism with cerebral complications. It is a bacillus somewhat resembling that of anthrax; it is readily stained with anilin dyes and by Gram's method, and is anaërobic. When inoculated into guinea-pigs, it causes inflammation of the serous membranes characteristic of rheumatism. Treboulet and Coyon² suggest that Achalmé's bacillus is associated with only the severe forms of rheumatism, and they have found it in some other cases associated with a *diplococcus*, which latter was found in all other cases of rheumatism examined. The

¹ *Ann. Pasteur Inst.*, Nov. 1897. ² *Bull. de la Soc. méd. des Hôp.*, Dec. 24, 1897.

diplococcus was facultative, anaërobic, and stained by Gram's method. The weight of authority, however, is in favor of the view that a diplococcus (*Diplococcus rheumaticus*) is the principal specific cause (*vide supra*). Streptococci of all bacteria have been most frequently found (Park) occurring as diplococci or short chains. The definitive cause of acute articular rheumatism, however, is still *sub judice*. In certain cases reported there was evidence of direct contagion.

Predisposing Causes.—(1) An *infective lesion* (septic wounds, attacks of angina, etc.) that has preceded for some time the appearance of the pain and articular manifestations may often be found, and this may be conceived to form a portal of entry for micro-organisms (Sacaze). The frequency with which an attack of tonsillitis precedes the development of acute articular rheumatism almost indicates a pathologic relation between the two diseases (Cheadle, Wade, Gerhardt, Packard). (2) *Seasons.*—The months of February, March, and April furnish the largest percentage of cases, though the disease is also quite prevalent in the remaining cold months; on the other hand, the disease may sometimes prevail in summer. Edlefsen and Newsholme have shown that the incidence is greatest when the ground-water is low. (3) "Catching cold" was formerly classed among exciting causes, but abrupt changes of temperature merely predispose to the disease. (4) *Climate.*—Rheumatism is most prevalent in temperate latitudes, being rare both in the cold and tropical zones. It is essentially an urban disease (Poynton). (5) *Occupation* is of importance, especially if it entail oft-repeated or prolonged exposure to the influence of wet and cold or to severe changes of temperature. Hence those who follow certain vocations are attacked with great frequency—*e. g.*, coachmen, laborers, sailors, and servant-girls. (6) *Age.*—Primary attacks are most common from fifteen to thirty-five years of age. Out of 655 cases, 80 per cent. occurred between the twentieth and fortieth years (Whipham). Cases are also rather numerous between ten and fifteen years, and I have met with 4 under the former age. Sucklings rarely suffer. (7) *Sex.*—Acute articular rheumatism is somewhat more common in men than in women, possibly owing to the fact that the former sex more often follows predisposing occupations. (8) *Hereditary influence* plays a causative rôle. (9) Conditions of ill health, particularly digestive and hepatic disturbances, seem to exert a slight effect. Preceding or accompanying the attack an infectious sore throat was noticed in 53 of 288 cases. (10) *Chronic endocarditis* renders its victims very prone to attacks of acute articular rheumatism, and some contend that the two diseases are etiologically one and the same. (11) *Choreic children* often develop rheumatism. Batton analyzed 115 cases; he found that within three years 11.3 per cent. of the children developed the disease, and after five years this total was increased to 20 per cent. (12) *Endemic and Epidemic Influence.*—In certain localities the disease is endemic, and epidemic incidence has been noted by McClymont, Newsholme, and others. House epidemics have also been observed.

An attack of acute articular rheumatism is not protective in character, but increases susceptibility. Of 288 cases, 45 per cent. of the patients had had one or more previous attacks (Thüs). In this respect the disease resembles certain other infectious diseases (pneumonia, erysipelas, etc.).

Clinical History.—Of the incubation-period nothing is known,

though *prodromata*, both local and general, may be observed. There may be malaise, slight fever, angina, laryngitis, etc., and last from a few hours to a day or two. The *invasion* is usually abrupt, with fever and synovitis, affecting one or oftener several joints, and a chill or a series of chilly sensations may accompany or precede the rise of temperature. The involved joints are tender, often red and swollen, and exhibit the local signs of a rapidly developed inflammation. *Pain* is a most prominent symptom. The medium-sized or larger *joints* (knee, ankle, and wrist) are first involved, and especially those of the inferior extremities; next the shoulder-, elbow-, and hip-joints; and lastly the fingers, toes, and intervertebral articulations. Quite unusual articulations may become implicated (*vide infra*). One of the chief peculiarities of the disease is in the fact that the joints that are affected are not all the seat of anatomic changes simultaneously, but that the process migrates from one joint to another from day to day, and often crosses from one side of the body to the other. Sometimes this occurs at longer intervals. Hence the number of joints involved at one and the same time may be either few or many.

In cases of average severity the general features are subordinate to the local symptoms. The fever is usually moderate, the temperature not exceeding 103° F. (39.4° C.), and the temperature-curve is of the irregularly remittent type, corresponding in severity with the joint-symptoms. Defervescence is by *lysis*. The skin is bathed in a copious perspiration which is not dependent upon a previous fall of temperature. Nervous symptoms are rarely observed.

The *general course* of the disease exhibits wide variations, both as to duration and intensity of symptoms, especially in children. It may not outlast several days, appearing with mild symptoms; on the other hand, cases sometimes persist for six to eight weeks. The latter instances are apt to show brief non-febrile periods, alternated with marked paroxysms, and similar cycles may be repeated. When the symptoms are distinct from the start the course may be briefer than when the features are of mild character. As will be seen hereafter, the disease frequently manifests complications, especially cardiac.

Leading Symptoms and Complications in Detail.—(1) **Joints and Surrounding Structures.**—As I have stated, pain is much complained of, and is greatly augmented by motion and by pressure of any sort. It may be out of all proportion to the degree of the anatomic changes. The joints affected are generally swollen (most markedly in the knees), and the swelling is due partly to effusion into the joint and partly to inflammatory edema of the periarticular structures. The sheaths of the tendons, the bursæ, and often the adjacent muscles and fasciæ exhibit inflammatory changes; hence it is usual to see an extension of the swelling for a variable distance from the joint, the backs of the hands often showing this to a marked extent. The skin may present a pink or rose-colored blush over circumscribed areas or taking the form of streaks.

In even *mild cases* there are usually two, three, or more joints involved, though it often happens that one bears the brunt of the disease, little complaint being made of others less severely implicated. Hence it should be a golden rule to examine carefully all the joints at each visit. Involvement of a single articulation (*monarticular rheumatism*) does sometimes occur, but the diagnosis of these cases offers great diffi-

culties. On the other hand, an existing polyarticular rheumatism may become centered in a single joint and there linger with great obstinacy.

In severe cases numerous joints may be invaded, with an involvement of the joints of the symphyses, of the jaw, of the ribs, and the sterno-clavicular articulations. Under these circumstances the patient assumes a dorsal decubitus, and seeks to relieve his excruciating pain by holding his limbs in a semiflexed position and absolutely motionless. If now an attempt be made to change his posture, he complains pitiously of darting pains in the affected joints. The *fugacity* of rheumatic arthritis has already been alluded to.

The inflammation, however intense, may quickly subside in one joint, while at the same time an acute disturbance appears in another. Usually resolution is complete, no trace being left of former inflammation, though the disease may recur in the joints primarily involved. Suppurative arthritis may supervene, though rarely, and its occurrence points indisputably to mixed infection. This complication may lead to ankylosis—a sequela which does not belong to pure rheumatism.

(2) **The Cardio-vascular Symptoms.**—The *pulse* is quickened to 100 beats per minute or over, but is soft and full, and when complications arise it shows special characteristics which are described in appropriate sections of this work. In rare instances it is very rapid, feeble, and irregular, apart from cardiac involvement. The results of a careful blood-count show a high grade of *symptomatic anemia*, which may develop with marvellous suddenness. Moderate *leukocytosis* is also present. Diplococci have been found in the blood in severe cases.

Great importance attaches to the *cardiac affections* that so frequently accompany this disease. They may arise in any case, even the mildest, or at any stage of the disease, and hence the conscientious physician cannot afford to neglect the matter of closely and regularly examining the heart. It must be recollected that no special symptoms announce the development of cardiac disease. At first we may note an increase in the febrile movement, more or less palpitation, sometimes dyspnea, and precordial pains, which often do not amount to more than a sense of soreness. There may also be attacks of angina pectoris of apparently purely nervous origin (Strümpell).

(a) The most frequent cardiac manifestation is *acute endocarditis*, which is present in 25 to 30 per cent. of the cases. We are, however, sadly in need of reliable statistics upon this point. It usually takes the form of simple (verrucose) endocarditis, and affects most frequently the mitral valves. But, though usually indicated by an apical systolic murmur, it is hard indeed to eliminate the functional murmurs that may also develop in the course of this disease. Unless combined with the symptoms detailed above, the presence of a blowing systolic murmur does not afford trustworthy evidence of the existence of acute endocarditis. I have witnessed two instances in which endocarditis preceded the arthritic manifestations. Church and Cheadle¹ state that “in a large majority of cases, if no endocardial murmur is present during the first ten days of an attack, the endocardium escapes.” While it rarely endangers life and may leave no trace, in the majority of instances the acute

¹ *Allbutt's System of Medicine*, vol. iv., p. 15.

endocarditis does not undergo complete resolution, but leads to sclerotic changes and terminates in incurable chronic valvular disease.

(b) Next in the order of frequency is *pericarditis*, which may or may not be combined with the former. In many cases the effusion consists of organizable lymph (often large in amount); less commonly it is serofibrinous and rarely becomes purulent or blood-stained. It is distinguished by its pathognomonic friction-sound, though also by other characteristic signs (*vide Pericarditis*).

(c) *Myocarditis* is often present to a slight extent in rheumatic endocarditis and pericarditis when these occur independently of each other, but more often and to a more marked degree when endo-pericarditis exists. Hence it is far less common than either endocarditis or pericarditis. The changes and symptoms occasioned will be discussed under *Myocarditis*. In this connection it should be pointed out that the condition weakens the cardiac walls and leads to dilatation of the ventricles (usually the left).

If we consider rheumatism an infectious malady, we can readily understand why the local manifestations should appear not only at the different articulations, but also in the cardiac structures, and, as we shall see, in other viscera.

(3) **The Skin.**—Rheumatism produces copious *perspiration*. The sweat emits a sour odour and gives at first an acid reaction, though later it may be neutral, and rarely alkaline. The temperature-curve in most cases is not materially influenced by the sweats. Occasionally the drops in temperature and the free sweats are concurrent, but the latter symptom is apt to persist despite the oscillations in the temperature. *Sudamina* appear, often in extensive crops. Among other *skin eruptions* less frequently observed are forms of erythema (especially *E. nodosum*) and urticaria, which latter may be associated with purpura (*urticaria hæmorrhagica*). The association of the latter condition with polyarthritis is known as *peliosis rheumatica*, though, according to some writers, this is not rheumatic in nature. Cutaneous ecchymoses, and even extensive hemorrhages into the skin and from the mucous membranes—a general hemorrhagic diathesis—may also be encountered.

Subcutaneous Rheumatic Nodules.—In 1881, Barlow and Warner called attention to the fact that during and after acute articular rheumatism, particularly in children and young adults, small subcutaneous nodosities attached to the tendons and fasciæ may in exceptional instances be observed. These small nodules are rather firm, movable, and usually painless. The skin over them is simply elevated, with no traces of inflammatory action. They are most frequently found at certain points of election (fingers, wrists, edge of the patella, malleoli, and over the back of the elbow), though also seen less frequently elsewhere; they may disappear and after a brief interval reappear. On *microscopic examination* it is seen that round and spindle-shaped cells enter into their composition. Riess believes them to be of embolic origin. I met with one fatal case of the sort which occurred in a male aged forty-two years, in which acute articular rheumatism was also complicated with endo-pericarditis and pneumonia. Most of the nodosities were of the size of a bitter almond. Cheadle considers that the eruption of large nodules signifies persistent and uncontrollable cardiac disease.

(4) **The Fever.**—The fact that the fever fluctuates materially in this affection has already been noted. It remains to be pointed out that if suppuration occur as a complication, the fever may be of the hectic variety; also that rarely hyperpyrexia is suddenly developed, and with it marked cerebral symptoms (restlessness, delirium, and sometimes convulsions, finally merging into stupor) are, as a rule, though not necessarily, associated. This serious condition commonly develops about the beginning of the second week. In my case cited above, it began on the sixth day. Delirium usually comes on either shortly before or after the acute development of the *hyperpyrexia*. The pulse becomes excessively rapid and feeble and physical prostration extreme. The temperature may rise rapidly with slight interruptions until it touches 108° or 109° F. (42.7° C.), and as the fever reaches its maximum death usually ensues. The temperature may continue to rise after death. The cause of “hyperpyretic rheumatism” is not definitely known. It has been claimed that the intemperate are most apt to be attacked, but this belief is not corroborated by many clinicians. In a case of my own, however, in which pericarditis with hyperpyrexia occurred, the patient was an “alcoholic.” The symptoms are probably due to an intense concentration of the poison upon the nerve-, and especially upon the thermal, centers.

(5) **The Muscular and Nervous Symptoms.**—It has been stated that the adjacent muscles and fasciæ may exhibit inflammatory changes. They may also show more or less swelling, and are often very tender to the touch, while in long-continued cases muscular atrophy ensues. The cause of this change is not clear, but the most likely view is that it results not so much from disuse of the muscles (the old theory), as from some trophic disturbance due either to the arthritis, or peripheral neuritis, or, to some extent at least, from extension of the rheumatic inflammation from the nearest articulation.

Mention has been made of the grave *nervous symptoms* that are attendant upon hyperpyrexia, but, independently of the latter condition, nervous phenomena may be present. There may be restlessness and sleeplessness (due to pain), but active delirium is exceptional in uncomplicated cases, and it is usually associated with a temperature of 104° F. (40° C.) or higher. In adynamic types, which are rare, low muttering delirium merging into stupor, and even coma, may be observed. Active mental symptoms are sometimes due to cerebral embolism secondary to acute endocarditis. When pericarditis is a complication, wild delirium, with or without hyperpyrexia, or the low muttering variety with stupor, is not unusual. The drunkard may develop *delirium tremens*. Coma, leading quickly to a fatal result, may develop without other previous or associated nervous symptoms, and DaCosta has reported cases in which a fatal coma was probably due to uremia. Rarely coma develops during the period of convalescence. *Convulsions* may be noted generally preceding the coma, though rarely as an independent symptom. *Melancholia* may arise in the course of the disease, but more frequently at its close. *Meningitis* must be numbered among the rarest of complications.

Chorea is a not infrequent sequel of this disease in children, and more rarely is associated with it. Of 554 cases analyzed by Osler, in only 88 were chorea and rheumatism associated. These instances may or may not be accompanied by acute endocarditis.

(6) **Pulmonary Symptoms.**—*Pleurisy* occurs, and is generally excited by, an extension of inflammation from the pericardium and pleura. The inflammatory process may be propagated through the diaphragm to the peritoneum. *Bronchitis* is sometimes present, but is rarely a part of the rheumatic morbid process; it is secondary, and is often occasioned by the co-operation of the factors that are at work in every disease in which enforced recumbency and great prostration coexist. *Broncho-pneumonia* may be produced. *Lobar pneumonia* rarely occurs, and is confined to aggravated cases, but pulmonary congestion is occasionally seen, and may prove fatal. Pulmonary complications also develop secondary to pericarditis, and especially to endo-pericarditis.

(7) **The Renal Symptoms.**—The *urine* is diminished in amount, is high-colored, and of high acidity and density. The standing specimen deposits urates. As in other infectious diseases, there is commonly present a slight febrile albuminuria, but acute nephritis is extremely rare. The chlorids are sometimes diminished, but rarely absent.

(8) **The spleen** is slightly enlarged in some cases. The *saliva* has sometimes an acid reaction, and, according to certain writers, the sulfocyanids are in excess. (9) Inflammation of the *parotid gland* (rheumatic parotitis) was met with in 3 cases by Courtois-Suffit and Beaufume.

Clinical Peculiarities of Acute Articular Rheumatism in Children.—The arthritic symptoms in children are in abeyance, while endocarditis and pericarditis are predominant, and these cardiac conditions may appear before the joint-lesions are observed. Endocarditis follows the joint-lesions twice as frequently in children as in adults. Parsons lays stress upon reduplication of the cardiac second sound, audible at the apex only, as an indication of the development of endocarditis. This sign is to be distinguished from reduplication heard at the base—*e. g.*, in Bright's disease. Acid sweats are slight in children. Rheumatic tonsillitis is common, and may precede, accompany, or follow attacks of rheumatism in children. Erythema is a frequent concomitant, and is often mistaken for scarlatina. The febrile movement is brief and hyperpyrexia less frequent than in the adult. The nervous features are more marked, notably chorea. Bareno¹ reports an instance in a newborn infant.

Diagnosis.—The acute development as a primary affection of poly-arthritis with fever, early tonsillitis, sudden anemia, moderate leukocytosis, and fresh cardiac murmurs, is a symptom-complex on which an assured diagnosis can be usually based.

Differential Diagnosis.—*Pyemia* must be carefully separated. In pyemia, however, the general condition is graver, fever precedes the local manifestations, and the fever-curve is irregularly intermitting. Rigors also occur in pyemia at varying intervals, accompanied by a steep elevation of temperature—symptoms that are absent in rheumatism. Again, suppurative processes in the various viscera and skin and slight jaundice appear in pyemia. Rheumatic symptoms fluctuate greatly, while the pyemic do not.

The multiple swelling of the joints which develops after childbirth is to be regarded as *septic* in nature. In these cases arthritis leads rapidly to suppuration, with more or less destruction of the joints. *Gout* will

¹ *Archives of Pediatrics*, Jan., 1902, p. 27.

be distinguished from rheumatism in connection with the consideration of the former disease (*vide* p. 432).

Monarticular rheumatism is with difficulty differentiated from a group of affections which simulate it closely. (1) The so-called *gonorrheal rheumatism* often affects a single joint, especially the knee; but in this disease there is usually a definite history of recent infection, and the local features (pain, swelling, etc.), unlike true rheumatism, are far more pronounced than the general. The course of gonorrheal arthritis is longer in duration, and is generally connected only with a single joint from the start; while acute articular rheumatism almost always begins as a poly-arthritis, with subsequent fixation in one articulation. Cardiac complications are rare in the former disease.

(2) *Acute osteomyelitis* is generally single, and is sometimes mistaken for rheumatism, from which it differs, however, in the localization of the lesions in a single joint from the start, the greater prominence of the local symptoms, and in the implication of the epiphyses and the shaft of the affected bone rather than the joint, and in the graver general symptoms from the time of onset.

(3) There is a liability to mistake the *acute arthritis* of infants for rheumatism. This attacks by preference the hip or knee, and is purulent inflammation due to pyemia (Townsend), hence having no relation to the disease under consideration.

(4) *Tubercular arthritis*, particularly in children, has been confounded with rheumatic monoarthritis. The former is less indurating, the swelling presented is less symmetric, the pain is greatest in the joint itself, and the course is far less acute than that of the latter.

(5) In the course of the *hemorrhagic diseases*, scurvy, purpura, and hemophilia, effusion into the joints, either hemorrhagic or serous in nature, occurs with great frequency and is associated with rheumatic pains. The differential diagnosis is to be formed from the tendency to hemorrhage, and in scurvy by the lesions of the gums. The absence of fever is usually decisive; unfortunately, it is frequently present in these joint-affections.

(6) *Glanders*, at the onset, may be mistaken for rheumatism.

Prognosis.—Recovery is the general rule. As in other infectious diseases, the chief danger springs from the great intensity of the type of infection, as manifested in hyperpyrexia with grave nervous symptoms, the development of the general hemorrhagic diathesis, etc.—happily rare occurrences in this disease. Certain complications, such as pericarditis, endopericarditis (especially common in childhood), pneumonia, etc., may render rheumatism grave or even hopeless, and rarely the endocarditis that complicates the disease is of the ulcerative variety and leads to fatal pyemia. Pulmonary embolism may occur and cause death.

The influence of personal factors may impede recovery, such as intemperate habits, great obesity, the existence of previous organic disease of the heart, or Bright's disease, etc.

Treatment.—(1) **Sanitary Environment, Diet, and Stimulants.**—The sick room should be well ventilated, and its temperature maintained at 65° to 70° F. (18.3°–21° C.), but draughts should be avoided. The patient should be lightly dressed in flannels and covered with a sheet of the same material. The *diet* should be liquid and nourishing, milk being the best food-article. Farinaceous matter, milk and Seltzer water,

buttermilk, egg-white, may be employed if milk cannot be taken in adequate amount. I begin the use of easily-digested forms of animal food soon after defervescence has occurred, but have immediate recourse to the earlier liquid or soft diet upon the return of pain and fever. An ordinary dietary is to be gradually resumed. *Stimulants* may be employed if indications for their use are present. The prompt treatment of tonsillitis, particularly among children and young adults, is important prophylactically.

(2) **Internal Therapeutics.**—The bowels should be opened early with calomel, followed by salines. There has been of late a surprising unanimity among clinicians in commending the use of the salicylates in the treatment of this disease—more so than at any previous time since their introduction. They are employed in most of the larger hospitals, both in Europe and America. Differences, however, relating to the mode of administration and the particular salt to be selected still exist. Wood¹ favors ammonium salicylate, for the reasons that it is freely soluble, is rapidly absorbed, and when given in sufficient amount quickly produces the symptoms that mark salicylic action, while, in addition, it is less depressing than the other salts of salicylic acid. It is best given in milk and is usually well borne. My experience with this salt in acute articular rheumatism, though as yet somewhat limited, has been satisfactory. Until the present time sodium salicylate has met with more general favor than any other single salt of salicylic acid. The pure acid is also used, though not to any great extent at the present day. As regards the mode of administration, the total daily amount taken is of higher importance than the size and frequency of the dose. The amount given in twenty-four hours should not exceed 2 drams (8.0), while often $1\frac{1}{2}$ drams (6.0) of the sodium or ammonium salicylate is sufficient. My method is to give gr. x (0.648) every two hours during the first day, or until the pain and other local features have largely disappeared; then the remedy is given at longer intervals, but not omitted entirely. In this manner fresh exacerbations are most probably averted. If the latter occur, however, larger doses must be instituted, so as to cut them short. Some recommend that the medicine be stopped as soon as the pain has been controlled. Lassere recommends methyl salicylate to relieve the pain. Some prefer salol to either the pure acid or the salicylates; in my experience, however, the use of this drug has been followed by good results. Doubtless the reason for this lies in the fact that salicylic acid can neither be introduced into the system in sufficient amount nor rapidly enough in the form of salol.

Kinnicutt has recommended the employment of the oil of winter-green, a salicylic compound which does not generally produce the unpleasant toxic symptoms so apt to be excited by the salicylates or salicylic acid. The dose is $\text{m}\text{x}-\text{xx}$ (0.60–1.25), given in capsules or in milk, to be repeated every two hours. Salicin (gr. x—0.648, every hour, increased to gr. xv—0.972) is sometimes efficacious and invariably agrees. Salophen, in daily doses of 1 dram (gr. xv—0.972, every four hours), may be substituted for sodium salicylate if the latter produces gastric disturbances after a few days' treatment; it is almost specific in its effects. Salophen passes through the stomach unchanged, to split

¹ *University Medical Magazine*, Jan., 1895.

into salicylic acid and acetylparalidophenol in the intestines. Sodium salicylate enemata (ʒj—4.0—of the salicylate and ℥x—0.60—of the tincture of opium in each injection) may be of advantage in certain cases. The remedy is slowly absorbed from the rectal mucosa.

The treatment with the salicylates or salicylic acid mitigates the fever, relieves the pain, and shortens the stay in bed by a few days, but does not curtail convalescence. The statistics of Williams go to show that the salicylate treatment also tends to protect against the development of cardiac complications, though it does not seem to influence the course of the complications once they are established. In my experience the alkaline treatment operates potently to obviate the occurrence of the heart-complications and shortens the period of convalescence, but exerts slight, if any, influence upon the fever-curve and pain. These facts led me long since to use, in addition to salicylates or other salicylic compounds, above indicated, an alkaline remedy, such as sodium bicarbonate, potassium citrate, etc., in sufficient doses to render, and then maintain, the urine of slightly alkaline reaction.

There are a few other remedies that should be referred to, and, although more or less serviceable, they are without specific influence. The foremost among these is antipyrin, but I have come to believe that safer and equally efficacious remedies have replaced this drug. Potassium iodid and the preparations of colchicum belong to this category, and should be tried. Their effects are most beneficial in cases that drag on after the acute stage is over. Good results have been reported from the use of aspirin (gr. vij—xv—0.436—0.972, thrice daily) in both acute and chronic rheumatism. Stengel has noted improvement from the use of antistreptococcic serum in three cases of protracted recurring rheumatism. Menzer has successfully treated a number of cases with a serum made from streptococci of human origin. It is also indicated in cases showing a pyemic temperature (Chipman).

(3) **Local Measures.**—These occupy a subordinate place in the management of acute articular rheumatism. Their number is legion, but only a few of the more valuable can be adduced here. In mild cases the affected joints should be wrapped in cotton batting or in flannel. If the pain is severe despite the use of the salicylates internally, fomentations as hot as can be borne or hot cloths lightly wrung out of Fuller's lotion (sodium carbonate, ʒvj—24.0; laudanum, ʒj—30.0; glycerin, ʒij—60.0; and water, ʒix—270.0) are beneficial. As salicylic acid is absorbed through the skin, it may be used in the following formula:

| | |
|--------------------|-------------------|
| R. Acid. salicyl., | |
| Lanolini, | āā. ʒiij (11.65); |
| Ol. terebinthinæ, | ʒiij (11.25); |
| Adipis, | ʒiij (11.65). |

M. et ft. ung.

Sig. Rub over the affected joints and follow by wrapping in cotton.

Methyl salicylate, by local application, is of service. It is put on the skin over the affected joints drop by drop, and the joint then enveloped in gutta-percha tissue and a flannel bandage applied to it. Cold compresses and the ice-bag to the joints have been strongly ad-

vised, particularly by German authors. The affected joints should be kept at perfect rest, and this is best accomplished either by padded splints and a roller bandage or plaster casts. Blisters near the joints involved and the light application of the Paquelin thermo-cautery are sometimes serviceable. Taylor¹ has successfully employed currents of hot air, applied by means of an instrument (electro-thermogen).

The treatment of the *complications* will be considered under their appropriate headings. Should, however, hyperpyrexia occur during the progress of the affection, it is to be relieved by cold affusions, since large doses of internal antipyretics are of themselves dangerous. It may also be stated that the cardiac complications—endocarditis, pericarditis, and endo-pericarditis—rarely require special remedies. If marked cardiac asthenia appears, as indicated by the feeble first sound, the salicylates may be replaced by salicin, which is less depressing in its effect upon the heart. Cardiac stimulants may be required. A copious pericardial effusion calls for paracentesis (*vide* Sero-fibrinous Pericarditis). Gürich² succeeded in curing 98 out of 125 patients with articular rheumatism by tonsillectomy.

During convalescence the patient should not be allowed to get out of bed too early. My own rule has been to keep him in bed for a week after the temperature has returned to the normal and after the pain has disappeared, except it be during the hot season. These precautions are taken to avoid the occurrence of relapses. After the patient goes into the open air he should be told to avoid cold, and wet in particular. During this period iron is to be employed until the blood-examination fails to show anything abnormal. For the stiffness and swelling that sometimes persist, or disappear very slowly after the acute attack, massage and the application of hot water or warm baths seem to yield the best results.

SUBACUTE ARTICULAR RHEUMATISM.

THIS is, as a rule, a sequela of acute rheumatism, and may occur, though rarely, in persons who have not had a previous acute attack. Both the local and general features are of a mild type, but the course is apt to be prolonged into two, three, or more months. Usually the local symptoms are confined to one or two of the larger joints, with little swelling or redness, and the pain is slight except on movement. The temperature rarely exceeds 101° F. (38.3° C.), and at times may be practically normal. Though the course is prolonged, the joints usually return to their normal state; occasionally, however, the disease becomes chronic. As in the acute form, so in the subacute, anemia becomes well marked and cardiac complications are not uncommon, particularly when the disease occurs in children.

The **treatment** embraces, in addition to the usual antirheumatics, the use of iron, quinin, cod-liver oil, and, when practicable, a change to a warm climate. The affected joints demand hot applications and massage.

GONORRHEAL ARTHRITIS.

Definition.—A septic synovitis caused by the gonococcus. It has no connection with true rheumatism. It usually manifests itself toward the close of an attack of gonorrhea, but it may develop during the active stage of the disease or at any period during the course of gleet.

Pathology.—The signs of ordinary synovitis are generally found in the affected joints, though, not rarely, the inflammatory process is periarticular (*gonorrheal tenosynovitis*). In these cases the inflammation may travel along the sheaths of the tendons for a considerable distance. Synovial effusion may occur, and rarely may be purulent, this being most frequent in gonorrheal inflammation affecting the wrist and hand. Gonococci have been found in the effusion, and it is now thought by many writers (Finger, Councilman, and others) that the gonococcus may be the only infective agent concerned in the morbid process. Others contend that the metastatic inflammation of the joints is due to the presence of pyogenic cocci—frequent companions of the gonococcus. Gonorrheal arthritis may be due in part to the absorption of ptomaines from the urethra. The disease is present in 2 per cent. of all cases of gonorrhea in males and rarely occurs in females (Gaither); it may follow any urethral discharge or may be associated with menstruation or leukorrhea. C. Lucas has collected 23 cases of gonorrheal rheumatism in infantile subjects of ophthalmia.

Clinical Symptoms.—Two leading varieties, acute and chronic, are encountered. (1) *Acute Gonorrheal Arthritis*.—This may be very mild, amounting merely to slight fugitive pains about one or more joints, without swelling or redness (*arthralgic form*). The typical, acute form, however, presents the symptoms of a severe fibrinous or sero-fibrinous inflammation of a single joint, developing quickly. The pain is often violent; there is swelling of the joint with extension along the course of the tendons, and the condition is obstinate. Unless pus be present (a rare event) the constitutional features do not correspond in severity with the local. There are many instances in which the complaint begins as a *polyarthritis*, with subsequent concentration upon one or two of the larger articulations, especially the knees or ankles. Fibrinous ankylosis usually remains as the resulting condition. In infants, however, this condition is transitory, as a rule.

Complications and Gonorrheal Septicemia and Pyemia.—*Acute endocarditis* may be of gonorrheal origin, and undoubted instances are common. In the inflammatory products of this condition Hering has found the gonococci, as has also Councilman, in the heart-muscles (gonorrheal myocarditis). Rarely, gonorrheal endocarditis assumes the ulcerative or malignant form. As the result of invasion of the blood by the gonococci, *suppurative arthritis* may develop and form a part of *gonorrheal septicemia*. Instances of severe, rapidly fatal general infection in gonorrhea are probably always associated with foci of suppuration in the urinary tract (Osler). I observed one case in which *pleurisy* was associated, and among the widespread complications *embolic*, *septic pneumonia*, and *iritis* deserve special mention.

(2) *Chronic Gonorrheal Arthritis*.—This occurs (a) as a serous effusion (*hydrarthrosis*), and (b) as a chronic inflammation of the articular and periarticular structures (synovial membranes, bursæ, periosteum,

and tendons with their sheaths). The former is usually monarticular, settling with especial frequency in the knees, and may be wholly painless. The latter is more or less painful—causes dense swelling of the joint, and frequently of the structures for some little distance above and below the latter. Both forms lead to great restriction of motion. The os calcis may be the seat of gonorrheal periosteal inflammation with or without exostosis. It is sometimes called the painful heel of gonorrhea.

The **diagnosis** cannot be determined apart from the history of urethral infection, or the detection of the gonococci in the blood or the joint-effusion. The acute form is distinguished from *acute articular rheumatism* by the more intense pain, the extent to which the peri-articular tissues are involved, and the negative character of the general symptoms. The chronic variety must be discriminated from *chronic synovitis* due to other causes, and this often proves a difficult task.

Treatment.—I have never seen the slightest benefit from internal medication in gonorrheal arthritis, except possibly from the use of mercury. J. C. Wilson¹ has obtained excellent results from massive doses $\text{m x-lx} = 0.60\text{--}3.75 \text{ t. d.}$) of the syrup of iodid of iron. There is much evidence at hand to show that chronic gonorrheal arthritis is favorably influenced by the injection of gonococcus vaccine.

Local measures, however, are of paramount importance. Absolute rest to the part is indicated, and the limb should be placed upon a splint; then after making an appropriate anodyne application (ungt. ichthyol. or ungt. belladonnæ), it should be bandaged as firmly as possible. In other instances complete immobilization in plaster-of-Paris dressing gives good results. In acute cases the patient should be anesthetized, and after the procedure, if pain be great, a hypodermic injection of morphin may be given. Dry heat, either sand-bags or the heating apparatus (oven), is useful. In *chronic forms* the aim should be to remove the effusion and swelling, and to restore the natural motility. For the latter two indications massage and passive movements are best. Hydrarthrosis may also be diminished by the use of the thermo-cautery, at intervals, and blisters. Willard urges removal of the infecting micro-organism by arthrotomy and free irrigation with antibacillary fluids.

VARIOLA.

(Small-pox.)

Definition.—Variola is an acute contagious disease, characterized by its sudden onset and severe period of invasion, followed by a remission of the fever and an eruption of papules, which pass through the stages of vesicle, pustule, and scab. The stage of pustulation is accompanied by secondary fever. Variola runs a variable course, but on the whole has become milder far in character in recent years.

Historic Note.—Smallpox has existed from the earliest antiquity in India, Africa, China, and other Eastern countries. During the thirteenth century (1241) it entered England, in the early part of the fourteenth Ireland, and in the latter part of the fifteenth Germany. In 1507 it was imported to America, and first appeared in the West

¹ Jacobi's *Festschrift*, 1900.

Indies; a little later (1520) the Spanish troops conveyed the disease to Mexico, where it destroyed not less than three and a half millions of people in its pestilential march. It was brought to the United States from Europe in 1649, and gained its first foothold in Boston, whence it progressed at intervals in a westerly direction to the western coast-line. During the Spanish-Cuban war the disease was transferred from Cuba to the Southern States, afterward spreading to many of the Northern and Western States. In numerous localities the cases multiplied to such an extent as to approximate at least an epidemic prevalence of the disease, although of unprecedented mildness. Variola, however, exhibits great variability in intensity in different epidemics. In the United States, for the years 1903 and 1904, there occurred 42,590 cases, with 1,642 deaths and 25,106 cases with 1,118 deaths, respectively (Wyman).

Pathology.—The eruption of small-pox consists in an inflammatory cellular infiltration of the *rete mucosum* and has four successive stages—(1) *Papular*, (2) *Vesicular*, (3) *Pustular*, (4) *Scab*.

(1) *The Papule*.—At first there is a hyperemia of the papillæ of the skin appearing as small red spots. These soon become round, discrete patches that may be rolled like shot under the skin, and then become elevated, owing to the increase in the cells in the *rete mucosum*.

(2) *The vesicle* appears at the apex of the papule, and results from a circumscribed elevation of the superficial layer of the epidermis in consequence of the mechanical pressure exerted by the fluid exudate, which is excited by peripheral inflammation. The vesicle is not unicellular, but is loculated (fibrinous reticuli), and contains serum, leukocytes, fibrin-filaments, etc. If a section of a vesicle be made early through the deeper layers of the *rete mucosum*, an area of coagulation necrosis is observed, due to the presence of micrococci (Weigert). The vesicle shows central umbilication, which corresponds with the necrotic area.

(3) *The pustule* is formed by the filling of the reticuli with leukocytes. Cellular infiltration and swelling of the true skin beneath the pustule occur, as a rule, as the result of diapedesis. Moreover, suppuration may involve the *cutis vera*, and as a consequence scarring results. In hemorrhagic small-pox the reticuli are occupied by an abundance of red corpuscles which have passed in from the adjacent blood-vessels, and may infiltrate the upper as well as the deeper layers of the epidermis surrounding the vesicles or pustules. The pustules may dry up, but commonly rupture, and in either case the result is (4) *scabbing*.

Recently Councilman, McGrath and Brinckerhoff have described the specific lesion as a focal degeneration of the stratified epithelium, accompanied by serous exudation and the formation of a reticulum.

The eruption has run an atypical and even abortive course in the cases occurring in recent years. An early maturation of the papules has been observed; in many cases they became solid, conical elevations with a small vesicle at the summit. W. M. Welch¹ states that the lesions seemed to involve only the outer epidermis and the layer of cells immediately over the papillæ.

The mucosa of the mouth, pharynx, and, rarely, the esophagus and the rectum may be the seat of a variolous eruption, and the plaques of Peyer may be somewhat swollen. The eruption also appears in the

¹ *Phila. Med. Jour.*, Nov. 18, 1899.

larynx, the trachea, bronchi, conjunctivæ and nasal mucosa, where ulcers rather than true pustules are seen.

Hemorrhagic small-pox presents extravasations occurring in the serous and mucous membranes, the connective tissue, the parenchyma of the various viscera, and also, though much less frequently, in the nerve-sheaths, bone-marrow, blood-vessel walls, and the muscles. In this form the spleen is firm (Ponfick, Osler), and the liver is sometimes enlarged and the subject of fatty degeneration. Hemorrhagic infarction of the lung occurred in 5 out of 7 cases examined by Osler.

Secondary Lesions.—The catarrhal inflammation of the larynx may extend in depth till it touches the perichondrium of the cartilages (perichondritis), and a croupous exudate in the larynx may often coexist with edema. Lesions are present in the lungs, some of them frequently (general bronchitis, bronchopneumonia), and others rarely (hypostatic congestion, lobar pneumonia), and *pleuritis* may be observed. Cloudy swelling, diffuse inflammation, and sometimes fatty degeneration of the *liver* have been noted; the *spleen* is enlarged and pulpy as a rule. The *heart* may show myocardial alterations—chiefly parenchymatous and fatty—and rarely endocarditis and pericarditis occur. The *kidneys* show cloudy swelling, an acute degeneration of the epithelium, more marked than in other infections, occurs. “An acute glomerulo-nephritis was found in 5 cases out of 54” (Councilman). Weigert found that at the commencement of the stage of suppuration the microscope revealed “small-pox cylindric masses” in the various viscera (coagulation necrosis).

Etiology.—Bacteriology.—The recent investigations of Councilman and his associates have resulted in the discovery of a protozoon in the epithelial cells of the lesions. There are two cycles of development, intracellular and intranuclear, the latter only occurring in small-pox. Transmission of these organisms by the dried epithelial scales may be responsible for the spread of the disease. These findings have been confirmed by Calkins and Howard and Perkins of Cleveland. M. Funck¹ found protozoa (probably the same organisms previously described by Pfeiffer) in all vaccinia pustules examined. They are usually from 1μ to 3μ in diameter, and larger cyst-like bodies filled with spores also occur. Iskigami² has also discovered protozoön-like bodies in the epithelial scales of the vaccine pustules, lymph, etc. Haushalter and Étienne³ consider the hemorrhagic symptoms in small-pox due to secondary infection with the streptococcus, since they have found this organism in the blood of those dead of hemorrhagic variola. Widai and Sabrazes have also noted the streptococcus in autopsies upon small-pox cases.

Predisposing Causes.—The *receptivity* for variola is wellnigh universal, and among the few who have enjoyed immunity were three distinguished physicians—Diemerbroeck, Boerhaave, and Morgagni. It may be said that one attack confers permanent immunity, but exceptionally a second or even a third may occur. *Vaccination*, also, if successful, affords future protection against variola, but to this rule exceptions are not infrequent.

Age.—All periods of life are liable to the disease, but the very young are affected in a relatively larger proportion than older persons. During the entire puerperal stage there is an increased liability to the disease.

¹ *Deutsch. Med. Woch.*, Feb. 23, 1901.

² *Jour. Amer. Med. Assoc.*, Dec. 6, 1902; cited from Sei-I. Kwai (Tokio) xxi.

³ *Saunders' Year-Book* for 1899.

It rarely affects the fetus in utero, and most babes even, who are exposed to the virus at the time of birth, will not take the disease if immediately and successfully vaccinated.

Sex is without influence.

Season.—This exerts little effect.

Race.—Among uncivilized peoples variola spreads with frightful rapidity, the negro and other very dark races being affected in larger numbers and more severely than whites, since they are not so generally vaccinated. A dread of the infection predisposes to its occurrence.

The Contagion; where Found; Modes of Conveyance and of Infection.—One case of variola is *prima facie* evidence of the existence of another, and that the poison from the latter was somehow transferred to the former. The specific poison exists in the blood and in the secretions and excretions (most probably), but mainly in the pustules and dry scabs and in exhalations from the lungs and skin. The contagion is conveyed principally from the sick to the healthy by the dust-like particles of the dried scabs.

Modes of Infection.—(a) *Inoculation* with either the blood or the contents of the eruption or the dissolved dry scabs is followed by variola. (b) Contact with, or proximity to, a patient suffering from small-pox is very apt to convey the poison, with resulting variola in the person thus exposed. To what distance the contagion can be conveyed through the air is not known, but it is probably considerable; and all authors are agreed that it is one of the most infective diseases with which we are acquainted. It is contagious from the earliest active stage to the end of convalescence, and possibly even during the stage of incubation. (c) Transmission by *fomites* is common, the poison adhering to clothes, body- or bed-linen, etc., and evidence is not wanting to show that the poison is highly tenacious of pathogenic power. Its vitality is retained after death, and the room occupied by a patient, the bedding, and the articles of furniture all serve to convey the disease unless thorough disinfection be enforced. The *infection atrium* for the poison into the system is probably the *respiratory tract*.

Clinical History.—**Incubation.**—This stage varies with the mode of communication of the poison. If following inoculation, the symptoms appear in six or seven days; when originating from infection, usually in twelve days, though this stage may be either lengthened by a day or two or shortened to an equal extent. During a portion of this period complaint may be made of certain ill-defined symptoms, but these are usually absent. **Invasion** is sudden and accompanied by characteristic signs. These are—a *severe rigor*, *high fever*, *headache*, and *intense lumbar pains*. Instead of the usual severe rigor, repeated chills, extending over twelve to twenty-four hours, may occur. The symptoms of the onset have been milder in the recent outbreaks, although similar in character to the severer types of former epidemics. During the preliminary fever the *respirations* are accelerated, the *pulse* becoming decidedly more rapid, and there may be generalized bronchitis. The *tongue* is coated and slight pharyngitis may exist. There are anorexia, general vomiting, and constipation or rarely diarrhea. Restlessness, delirium, and stupor are the principal nervous symptoms observed. Infective *albuminuria* is common. In the female menstruation is apt to occur.

The **physical signs** referable to the lungs are few, and consist of a

few dry and, later, moist râles, heard on *auscultation*. *Palpation* detects splenic enlargement. From the second day the so-called *initial rashes* may appear: (a) the *diffuse scarlatinous eruption*, which in no way differs from ordinary *scarlatina*; (b) the *measly eruption*, which may be diffuse and present a striking similarity to that of measles. Either associated with these or occurring independently there may be a hemorrhagic eruption (usually purpura), the petechiæ coming out by natural selection, mainly upon the hypogastric region or the inner surfaces of the thighs and in the axillæ (Simon). The initial rashes occur in a considerable proportion of cases (10–15 per cent.). The *stage of invasion* lasts three days as a rule. The temperature then declines rapidly, while at the same time the true *variola eruption* appears upon the skin and mucous surfaces. It develops first upon the face, particularly upon the forehead and the hairy scalp, and spreads in a downward direction till it reaches the legs, where it last appears. The skin in the femoral triangle rarely shows the true variolous eruption. Each pock passes through the various stages noted in the pathologic description—viz., papule, vesicle, pustule, and scab; and when the stage of pustulation has been reached a secondary fever develops. During the following remission of fever the headache, lumbar pains, etc., subside. The fever of suppuration which then succeeds is accompanied once more by marked constitutional disturbances, particularly nervous derangements (wild delirium, etc.), and at this time complications are also apt to develop. On the eighth or ninth day of the eruption (the twelfth or thirteenth day of the disease) the pustules begin to dry up, forming yellow crusts; the redness and swelling of the skin subside; and two or three days later the scabs loosen and are thrown off. During this stage the fever again declines in company with the constitutional symptoms, and convalescence ensues. As previously stated, when suppuration involves the true skin scars are the inevitable result, and these remain to the end of life. The hair drops off sometimes, even to the extent of total alopecia, but is generally renewed.

The general *course* described above is that of an average case, but the cases met with in the recent epidemic appearances in numerous sections of this country have been unusually mild, and also manifested strange features; and to these the terms “modified” and “mitigated” small-pox may be appropriately applied. Although not all cases were equally mild, many of them were practically ambulatory, since they would not remain in bed after the eruption appeared, and this was also true of those unprotected by previous vaccination. There was little or no secondary fever and desiccation was rapid. Says W. M. Welch,¹ whose experience is unparalleled: “I must say I have never seen cases present, uniformly, so mild a type as during the present year (1899), nor have I been able to find in the vast amount of literature published on the subject any account of a similarly mild epidemic in this or any other country.” During the last two years the disease has resumed a more typical course, both as to symptomatology and severity of type.

Leading Symptoms and Complications.—(a) **Eruption.**—The eruption in the more typical cases appears at the end of the third or on the fourth day, coming out first upon the forehead, particularly along the border of the hairy scalp, and spreading in a downward direction in

¹ *Loc. cit.*

PLATE I.

VARIOLA (Royer).

regular progression. It appears in the form of slightly elevated maculæ, which are at first of a pale red color, and later assume a darker red hue, resembling small fleabites. These increase in size during the next forty-eight hours, at the end of which period they are developed into (1) *papules*. The change of character is accompanied by intense itching and burning of the skin-surface. To the feel they are papular, like shot under the skin. The eruption is always most abundant upon the face and scalp, while the hands and fingers are the next most favored seats. At the end of the third day (the sixth day of the disease) the conical apices of the papules contain liquid, forming thus (2) *vesicles*. The latter increase in size till the entire papule is converted, at the same time acquiring more and more decidedly a central umbilication. Puncturing a vesicle does cause it to collapse, but allows only a small portion of its liquid contents to escape, owing to its reticulated character. As the vesicle increases in size its contents become opaque, and in three days more, or about the sixth of the eruption, the vesicles become (3) *pustules*. Umbilication now disappears, and the pustule looks full and well rounded, and is surrounded by a red border or "halo." If the pocks be close set, as on the face, wrists, and fingers, the intervening skin is inflamed and swollen and the itching and burning become almost intolerable. The pustules may coalesce along their edges, and thus the

FIG. 16.—Temperature-chart of a case of variola, from a patient in the Municipal Hospital, Philadelphia. A. F.—, aged three years; not vaccinated.

eruption becomes confluent. The eyes are closed as the result of swelling and tumefaction of the face, and the hands and feet assume a rounded, ball-like appearance. The face, as a whole, is markedly misshapen and is ultimately disfigured. When the pus is not liberated (a comparatively rare event), its desiccation begins on the ninth day (the twelfth day of the affection); if the pustule is ruptured earlier (as when confluence occurs, it begins at an earlier day. (4) The *scabs* now form, and remain until about the twelfth day of the eruption, and when pits or scars result they gradually fade until they remain as permanent whitish spots.

The eruption upon the mucous membrane develops simultaneously with that of the skin, and among favorite surfaces for its appearance are the mouth, tongue, soft palate, and pharynx (causing *dysphagia*), the nasal chambers (causing *coryza*), the larynx (causing *hoarse-*

ness), the trachea and bronchi (causing *bronchitis*). This mucous efflorescence does not proceed to the development of pustules, but forms ordinary ulcers as a consequence of early maceration of the superficial layers of the mucosa, and these ulcers also may become confluent.

The *skin* presents certain complications that are always secondary and are deserving of mention (erysipelas, abscess, gangrene, bed-sores).

(b) **The Fever.**—The temperature at the onset rises rapidly, and may touch 103° or 104° F. (40° C.) on the first day, its range being high and of the continued type during the invasion period. Evening temperature of 105° F. (40.5° C.) or higher may be observed, and in three days (or with the first appearance of the papules), the temperature remits, but does not intermit in true variola. It remains at a low elevation till the stage of suppuration is reached, when a fresh rise occurs. This secondary fever-curve is apt to show exaggerated points of elevation and deep remissions. The latter are generally the result of septic absorption (the fever of suppuration). Secondary fever, since the variolous infection has grown milder in type, is often slight or may be wanting (*vide supra*). This period lasts from one to three or four days. When desiccation of the pustules begins, defervescence also commences, and proceeds in a gradual manner by lysis. There may be a post-variola rise, and if so, its presence is to be attributed to some sequel or other.

(c) **The Circulatory System.**—The *pulse* is soft and much accelerated (100 to 130) and of good volume during the invasion stage. It is slower during the period of remission, only to be greatly increased in frequency during the second stage of fever. During the latter period it may, owing to cardiac failure, become very rapid, and finally irregular or even intermittent. Simple *endocarditis* rarely, and *pericarditis* somewhat more commonly, occur as complications. In typical cases the leukocyte curve shows two exacerbations—one about the eighth day, another from the twelfth to the fourteenth day.

(d) **Respiratory Tract.**—The *laryngitis* and *pharyngitis* which are due to the presence of pocks in the respiratory mucosa have already been mentioned. *Laryngeal perichondritis* with edema of the glottis, the latter perhaps being the result of a direct extension of the pock-ulcers to the perichondrium, may arise; it is ominous. Chief among the grave secondary complications is *bronchopneumonia* (inhalation pneumonia); and *lobar pneumonia* also occurs, though rarely. *Pleurisy* is not infrequent, particularly as an associated condition in bronchopneumonia.

(e) **The Digestive System.**—The variolous efflorescence in the buccal and pharyngeal mucosæ may be an agency in predisposing to a secondary inflammation in adjacent organs—*e. g.*, suppurative otitis media, suppurative parotitis, pseudo-diphtheria, etc. *Palpation* almost always shows an enlarged spleen, and not infrequently an enlarged liver. The vomiting which is usual at the onset is due to a catarrhal condition of the stomach. Constipation is common, but diarrhea is also sometimes met with, being excited by a catarrh of the large intestine, and is especially common in children. The pocks may be found in the rectum and they sometimes excite dysenteric symptoms.

(f) **The Nervous Symptoms.**—The chief of these have been already pointed out. *Violent delirium* (previously alluded to) may be followed by fatal *coma*, and in children *convulsions* may be seen. Very rarely paraplegia has been observed during the attack, though it is more com-

mon during the convalescence, and is then due to different causes, such as peripheral neuritis and disseminated myelitis (Westphal). *Multiple neuritis* may be a sequel or the pharyngeal nerve may alone be affected. Among other conditions rarely arising during convalescence are insanity, epilepsy, aphasia, and hemiplegia.

(g) **The joints** may be swollen and painful after small-pox, and in rare cases periostitis may be observed.

(h) **Renal Symptoms.**—Welch and Schamberg¹ made analyses of the urine in 128 cases of variola, and found the presence of albumin in 65 per cent. and tube-casts in 45 per cent.; they believe that the albuminuria in most cases is the expression of a structural change due to the small-pox poison. The clinical symptoms of variolous nephritis are mild as a rule. Hemorrhagic nephritis may occur, but it is rare.

(i) **The Special Senses.**—The pustules may form upon the conjunctivæ and eyelids, and several important conditions result from this variolous involvement of the eye—viz., conjunctivitis, keratitis, choroiditis, and panophthalmitis. Hebra met with ocular complications in 1 per cent. of 5000 cases of small-pox. Otitis media has already been mentioned.

Special Clinical Forms.—There are two unusual types of variola that are important in being severer than the moderate (discrete) form.

(a) **The Confluent Form.**—This is the result of an abnormally severe infection, and is less common than formerly. The *ushering-in symptoms* are very severe, and the eruption may appear as early as, or even before, the third day, when the temperature remits. The separate papules are vastly more abundant and close-set; and after the stage of pustule is reached the face and hands present an uninterrupted area of suppuration. The deformity of the countenance is correspondingly pronounced. Naturally the *local symptoms* are intense and the fever and its concomitants are in exact proportion. The *nervous symptoms* often predominate. Salivation is frequent. The eruption may also entirely cover the mucous surfaces. The *lymphatics* of the neck may be greatly swollen—a circumstance that contributes to the facial disfigurement. The various complications previously adduced are of comparatively frequent occurrence, and following these a general pyemic process may develop. When death occurs it is usually preceded by the *typhoid state* (typhomania, tremors, a rapid, feeble pulse, dry, brown tongue, and diarrhea). On the other hand, if recovery ensues, it is tardy.

(b) **Black Small-pox.**—In this form the blood is much changed, so that hemorrhages into the skin, mucous membranes, and various viscera occur. It is important to distinguish several sub-varieties, as follows: (1) A *benign* form, in which blood is infused into the pustules when patients are allowed to leave their bed too early in convalescence. Here the condition is due to the effect of gravitation, and hence is confined almost solely to the lower extremities. (2) Doubtless the ordinary variolous eruption may become *slightly hemorrhagic* without aggravating the constitutional condition. (3) A *dangerous hemorrhagic* tendency may be manifested. During any of the eruptive stages—papular, vesicular, or pustular—hemorrhages may occur into the eruption, and, moreover, free bleedings may take place from the various mucous surfaces. The initial symptoms are usually intense, the eruption abundant, and in consequence of the hemor-

¹ *Phila. Med. Jour.*, Dec., 1902.

rhages collapse often occurs. The most serious complications, pneumonia, diphtheria, and nephritis (followed by uremia), are also apt to develop and terminate life. This and the subsequent sub-variety are truly anomalous. (4) A not uncommon form is met with in which the *acute hemorrhagic diathesis* develops during the period of invasion. Its onset is characterized by the usual symptoms intensified, and as early as the second day ecchymotic patches appear upon the skin surface and grow rapidly by peripheral extension, the mucous surfaces also showing more or less extensive ecchymoses. The variolous eruption rarely appears, though occasionally shot-like papules may be detected. The temperature may be slightly elevated, but is rarely high. Death often occurs before the time for the appearance of the characteristic eruption.

There are also varieties of small-pox that pursue an abnormally mild course. Of these (c) *varioid* deserves first place. By this term is usually meant small-pox occurring in individuals who have been protected by a successful vaccination, but it may also be the result of natural insusceptibility. Hence variola and varioid are one and the same affection. The *initial symptoms* of varioid do not differ either in character or severity from those of true variola, but the general course of the attack is peculiarly prone to manifest irregularities. In the pre-eruptive stage an erythematous rash is very common, and its appearance is regarded by many as being of value in discriminating varioid from variola.

When the *regular eruption* appears, the fever falls to normal and remains there. The rash comes out by the end of the first or on the second day, the papules being scanty, but may appear first upon the trunk, not the face. They are identical with the papules of variola, as is true also of the vesicles; but pustulation rarely develops, since resolution takes place, but, as a rule, before the latter stage is reached.

The *secondary fever* is either very slight or entirely wanting. The mucous surfaces are affected only slightly. Papules and vesicles may be found in close proximity; not so in variola. Desiccation begins between the fifth and seventh days of the eruption (the eighth and tenth of the disease), and hence, as compared with variola, the course is cut short and serious complications almost never occur. There has been noted the same marked tendency to extreme mildness of phenomena that characterize variola in the recent epidemics.

(d) An *abortive* form is occasionally observed. It is characterized the intensity of the invasion symptoms, but these subside, and the patient enters at once upon a stage of speedy recovery.

An exceedingly mild type may arise during seasons of epidemic prevalence of the disease, either with or without a scanty and undeveloped eruption; the diagnosis is made from the etiologic circumstances.

Diagnosis.—With a clear history and the presence of the characteristic features a positive diagnosis is a simple problem. But at any period before the papules are fully developed it may be confounded with certain other acute infections, notably cerebro-spinal meningitis, typhus fever, scarlatina, and measles. After the variolous eruption makes its appearance the disease may be confounded with impetigo contagiosa, pustular syphiloderm, and varicella. Councilman¹ advocates two methods to decide the diagnosis: one is by corneal inoculation on the rabbit, the other direct microscopic examination of the suspected lesion.

¹ Osler's *Modern Medicine*, vol. ii, page 295.

Differential Diagnosis.—In *typhus fever* the onset is very like that of small-pox. The former may, however, be distinguished by its peculiar etiologic factors, especially its origin by importation or its non-prevalence in the vicinity; the appearance of the eruption, first upon the trunk (chest and abdomen) in the form of maculæ, and later becoming petechial. Moreover, in typhus the temperature does not remit with the appearance of the eruption.

From hemorrhagic small-pox *typhus* is sometimes distinguished with great difficulty. In the former death often occurs before the eruptive stage is reached. In typhus shot-like papules are never detected, whereas they are sometimes found in hemorrhagic small-pox.

Hemorrhagic small-pox may be simulated by *cerebro-spinal meningitis*. If the history be not clear, lumbar puncture will settle the doubt.

Scarlatina may early be distinguished from the erythematous (scarlatinous) rash which often precedes the appearance of the variolous eruption; this is, as a rule, neither so intense nor so uniformly distributed over the skin-surface of the body as in true scarlatina. *Hemorrhagic scarlatina* may readily be confused with black small-pox.

The *macular stage* of the eruption may be confounded with *measles*. The absence of the characteristic prodromes and symptoms of invasion belonging to the latter disease, the redness and swelling of the conjunctivæ, the photophobia and marked coryza, the stubborn cough, and increased fever after the eruption appears, make the separation easy, as a rule. After the maculæ develop into hard, shot-like, conical papules the scales are turned in favor of variola.

Impetigo contagiosa presents no initial stage; it begins as vesicopustules (not papules) which appear "on the normal skin and are superficial and enlarge by peripheral extension, often attaining the size of a 10-cent piece and having a flat appearance" (W. M. Welch). The patient may infect new areas by scratching. Scars do not result.

Syphilis distinguishes itself by a milder initial stage, by the indurated base of the pustule, by the appearance in crops of the skin-lesions, and by the polymorphous character of the latter. There is neither umbilication nor characteristic pitting after the scabs fall, but a coppery hue.

To differentiate certain mild cases of discrete small-pox (in the non-vaccinated) and varioloid from *varicella* is difficult. In the table below, however, will be found contrasted points of distinction:

| VARIOLA. | VARICELLA. |
|--|--|
| <i>History.</i> | |
| Absence of previous attack. | Same. |
| Previous or existing case in the vicinity. | Traceable to previous or present case of varicella. |
| Not successfully vaccinated. | Negative. |
| Occurs at any age. | More commonly in childhood. |
| Characteristic pre-eruptive stage—rash on the third day. | Eruption not preceded by prodromes; develops more rapidly. |
| Sacral pain, high fever, and vomiting common. | Quite uncommon. |
| <i>Eruption.</i> | |
| Appears first upon the forehead, extending downward. | Appears first over parts covered by clothing. No regular procession over the body. |

VARIOLA.

VARICELLA.

Eruption.

Vesicles uniform in size, umbilicated, and deeper seated.

Eruption contains serum, later pus.

Most abundant on face and fingers.

Various stages of eruption observed at points removed from each other.

Pin-prick does not cause collapse of vesicles, being multilocular.

Secondary fever usually present.

Vary in size, sharply elevated, rarely umbilicated, and feel soft and velvety.

Only serum, giving pearly translucency.

Most abundant upon back and lower extremities.

Various stages side by side.

Does cause collapse, being unilocular.

Absent.

Park found that monkeys are susceptible to inoculation with small-pox virus, whereas that taken from cases of varicella produced no result.

Prognosis.—The prognosis depends upon (a) the degree of severity of the type, the severer forms (confluent and certain of the hemorrhagic) being grave. The hemorrhagic variety, in which large ecchymoses suddenly develop, is almost invariably fatal, and often before the cases have advanced to the eruptive stage. The aggregate number of pocks that appear and the gravity of the infection are, as a rule, proportionate.

(b) The prognosis is modified by *individual peculiarities* (age, intemperance). Thus it is more fatal in the very young than in older subjects, more fatal in the intemperate than in the temperate, and so on.

(c) Complications increase the death-rate considerably. Of these, bronchopneumonia, lobar pneumonia, acute nephritis with uremia, septicopyemic conditions, pseudo-diphtheritic angina, and pericarditis are most potent for evil. Among the foremost serious symptoms may be mentioned excessive vomiting, wild delirium, coma, a temperature of 106° F. (41.1° C.) or over, urgent diarrhea, and dysentery.

The death-rate has been computed to be between 15 and 30 per cent., varying, however, with each epidemic. Welch's statistics from the Municipal Hospital, Philadelphia, are as follows: In 2831 cases of variola, 54.18 per cent., while in 2169 cases of varioloid only 1.29 per cent. died. During the recent widespread prevalence of the disease in the United States the mortality rate was unprecedentedly low. Welch and Schamberg found the death-rate in unvaccinated persons 49.45 per cent. in the blacks and 44 per cent. in the whites.

Treatment.—The varied indications in the treatment of small-pox will be considered separately:

(1) **Prophylaxis.**—The rules that have been laid down elsewhere (*vide* Treatment of Typhoid Fever) for disinfection in infectious diseases must be rigidly enforced in this affection. Quarantine (*public and private*) must be secured if the deadly progress of small-pox is to be averted. Absolute isolation cannot be carried out successfully in private houses, and in view of this fact special, well-equipped hospitals should be provided for the reception of the disease. It is important also to remember that persons who have been afflicted with the disease cannot with safety to others resume their former places, either in the family or in society at large before they are completely convalescent. The best means of prevention, however, is vaccination (*vide* p. 200).

(2) **General Management.**—The room occupied by the patient should

be large and freely ventilated (an essential matter, though strong drafts are to be avoided), and all carpets, curtains, and articles of furniture not absolutely needful should be removed.

The *diet* should receive careful attention, and should be varied according to the stage of the affection. During the initial stage it must be restricted to liquid nourishment (milk, animal broths, etc.), and in addition cooling drinks, including ice, lemonade, and other of the various fruit-juices (diluted). During the stage of remission we may add soups, jellies, eggs, toast, and with the onset of the stage of suppuration a supportive diet, reinforced by the judicious use of stimulants, is an essential part of the treatment. Light forms of nourishment must now be given in definite quantities and intervals.

(3) **The fever and associated symptoms** during the invasion stage are best controlled by the cold or gradually cooled baths, which possess all the advantages in this disease that they command in typhoid fever. Cold sponge-baths, the ice-cap, or the cold pack may be resorted to if cold immersion baths are not accessible to the patient. The internal antipyretics must be given with a sparing hand, if at all, and only as antiseptic agents, on account of their depressing effects.

The therapy of this stage also embraces the treatment of certain symptoms. The vomiting may be incessant and exhausting, and chipped ice, champagne, dilute hydrocyanic acid, and cocain hydrochlorate should be tried in the order mentioned. If diarrhea be severe it should be checked (though neither wholly nor suddenly) by the use of arsenite of copper, the acetate of lead (gr. ij—0.1296) and opium (ext., gr. $\frac{1}{4}$ —0.0162), in combination, or by bismuth salicylate (gr. v—0.324) and β -naphthol (gr. iij—0.1944). The nervous symptoms are usually restrained by the cold affusions, but occasionally a wild delirium may necessitate a combination of sodium bromid (gr. x—xv—0.648—0.972) with the deodorized tincture of opium (m_v—0.333), given every two or three hours. Very often the wise administration of stimulants removes all necessity for the use of further means of overcoming the nervous symptoms. The catheter must be used if retention of urine should occur. For the intense pains that belong to this stage no other remedy can be compared with morphin sulphate (gr. $\frac{1}{8}$ to $\frac{1}{4}$ —0.008 to 0.016), to be administered hypodermically, and repeated if necessary.

(4) As previously stated, the **eruption** appears with the termination of the initial febrile period, and deserves the closest attention. The indications are twofold: (*a*) to limit the eruption as far as is possible, and (*b*) to modify its course, so that extensive suppuration and consequent disfigurement may be prevented. Ablutions with lukewarm water, to which may be added some antiseptic (carbolic acid and glycerin, or, better, a mercuric-chlorid solution—1 : 5000 or 1 : 10,000) will be found of great use. To prevent pitting many local applications have been used. Formerly, a common mode of treatment was to open the pustules as early as possible and touch them with silver nitrate—either in the solid stick or brushed over in a strong aqueous solution. The formula of Schwimmer, herewith given, gave excellent results in a case of my own:

| | |
|-----------------------|------------|
| R. Phenolis, | 4.0-10.0 ; |
| Ol. olivæ, | 40.0 ; |
| Cretæ-præparat., | 60.0. |
| M. et ft. pastamolis. | |

It has been recommended to touch each pustule with carbolic acid, and then to apply this agent in equal parts with the oil of thyme (Sansom). It is important that only a certain proportion of the pustules be touched at once. Welch and Schamberg recommend painting the surface with tincture of iodine. The parts must be kept aseptic and clean, while irritation from scratching, etc., must be carefully avoided. Moore and Fingen have recommended the use of red curtains or shades to cut out certain chemical rays. N. R. Finsen has advocated the exclusion of daylight, especially the chemic rays, by means of a red light, the skin being rendered very sensitive to light by the small-pox infection. The supposed effect is to prevent pustulation, and hence the formation of pitting of scars. A saturated solution of potassium permanganate applied to the exposed regions has been recommended instead of Finsen's red-light treatment, which acts similarly in that it excludes certain chemical rays. But as the result of treatment of test cases by Schamberg, Ricketts, and Byles, the claims made for red light by Finsen have not been substantiated. The daily use of scrub-baths, though severe, appears to prevent vesiculation and the further progress of the eruption, thereby avoiding pitting (S. M. Wilson).

During convalescence, warm baths, with the free use of carbolic soap, are to be given at intervals of two days until several baths have followed the separation of the crusts.

(5) **The Period of Remission of Fever.**—There are very rarely any symptomatic indications apart from those presented by the eruption. It is of first importance, however, to support the powers of the system.

(6) **The Suppurative Stage.**—All measures tending to support the strength of the patient are needed—the mineral acids, with the elixir of calisaya, quinin, strychnin, etc. Stimulants are often required, and it may become necessary to give them unsparingly, the character of the pulse being the physician's principal guide as to dosage. Gradually cooled baths of the usual duration or warm baths somewhat more prolonged give excellent results. The ulcers in the mouth and throat are best relieved by the use of a saturated solution of chlorate of potassium in water as a gargle or in the form of an atomizer spray. Ice allowed to melt in the mouth is also valuable. Hemorrhages demand full doses of ergot subcutaneously. Internally, the tincture of the chlorid of iron, gallic acid, the mineral acids, or turpentine may be administered.

The *complications* are not numerous, and are for the most part secondary. By frequently changing the position of the patient when bronchitis is present, and by encouraging him to cough frequently, as well as by the timely use of stimulants and the proper care of the mouth, pulmonary complications can often be obviated. Should lobular pneumonia occur, the plan of treatment which is likely to meet with most success may be briefly put thus: Free stimulation with alcoholics and other cardiants, the assiduous use of cold sponges or gradually cooled baths, and nourishing foods. *Laryngeal perichondritis* with edema

of the glottis may suddenly demand tracheotomy. To avoid the development of *bed-sores* an air-cushion should be provided, if needful. Care should also be exercised to prevent ocular complications, and their occurrence demands supportive treatment. I have much confidence in the use of cold compresses, instilling into the eyes at the same time a solution of boric acid (gr. x to xv—0.648 to 0.972—to fʒj—30.0).

(7) **Special Modes of Treatment.**—These would be found to be numerous, were we to enumerate all of them, but only those based on the principle of antiseptics are worthy of notice. According to one plan, which has many advocates, antiseptic agents are administered internally. The remedies that have been most frequently employed in this manner, and with perhaps the most promising results are the sulphocarbolates, salol, sodium salicylate, carbolic acid, creasote, mercuric chlorid, and the sulphites. R. A. Woodson¹ adopted as a plan of treatment in the Holguin epidemic, daily scrub-baths, 1–2000 mercuric chlorid, and open-air treatment. Du Castel advises at the time of the eruption injections of ether morning and evening; during the day a solution containing 2 or 3 grains of the extract of opium is to be given in divided doses.

Kinyoun, Lundmann, and Bécélère have used the serum from vaccinated subjects (human beings and the lower animals) or from variolous patients in advanced stages of the disease in the treatment of small-pox. The cases, however, are insufficient to warrant deductions.

Special Methods of External Medication.—Talamon recommends a mercuric-chlorid spray for small-pox vesicles and pustules as follows:

| | |
|-------------------------|---------------|
| R. Mercuric chlorid, | gr. xv (1.0); |
| Tartaric acid, | gr. xv (1.0); |
| Alcohol (90 per cent.), | fʒjss (6.0); |
| Ether to make | fʒjss (45.0). |

Sig. To be applied as a spray three or four times daily for one minute.

It is essential to exercise the precaution to protect the eyes, which may be covered by layers of cotton dipped into a saturated solution of boric acid. Talamon advises the commencement of his method on the first day of the eruption, the application to be preceded with a vigorous washing of the face with soap, which may be rinsed off with boric acid and then dried with absorbent cotton. After the spray has been used the face should be covered with a layer of a 50 per cent. glycerolate of mercuric chlorid in order to keep the skin continuously aseptic. After the fourth day the number of sprayings per diem is gradually lessened, so that by the seventh day they may be discontinued; but the application of the glycerolate should be continued.

Talamon added, in the confluent and other grave forms of the disease, general mercuric-chlorid baths, lasting for three-quarters of an hour to an hour. The buccal and pharyngeal eruption is to be treated by gargles and lotions of boric acid.

Convalescence.—A furfuraceous desquamation may persist for a considerable period; it is to be treated by applications of oils containing some disinfectant. Convalescence is not established until desquamation ceases.

¹Saunders' *Year-Book*, 1901.

VACCINATION.

Historic Note.—One of the first steps in preventive medicine was the practice of inoculation as a method of protection against the infection of small-pox. It had been practised in China and other Asiatic countries for centuries, and Lady Montague, the wife of an English ambassador to Turkey, early in the eighteenth century introduced it into England, after which time and until vaccination was known, it was very extensively practised there.

Pus taken directly from a small-pox pustule was introduced beneath the epidermis, and the person inoculated developed variola, though in a milder form than when arising from ordinary infection.

The objections to this method were that it did not always produce a mild form of variola, a small percentage of cases having a fatal termination, and that, however mild the attack, other unprotected persons brought in contact with it were as liable to contract virulent small-pox.

In a paper published in 1798, Edward Jenner, a physician of Gloucestershire, England, and a pupil of John Hunter, first made known to the world the value of vaccination. Twenty years previous he had observed that persons employed in dairies, who were accidentally inoculated with cow-pox were insusceptible to the contagion of small-pox, and, after experimenting all these years, he became satisfied that inoculation with the vaccine lymph was a preventive against small-pox. After the publication of his paper he was subjected to ridicule and abuse by the profession, but through his persistence he was finally allowed to practise his method of vaccination in the wards of a hospital, and in the course of a few years it became generally recognized and was practised in France and America, as well as in England. Later, the method fell into disrepute for a time, owing to the fact that certain persons who had been vaccinated subsequently contracted the disease, it not being known then that a revaccination was necessary from time to time. At present it is generally held that successful vaccination imposes complete immunity against variola.

Vaccinia, or cow-pox, is a mild eruptive disease that occasionally occurs among cattle, a similar disease being produced in them by inoculation with the small-pox virus from man. It is communicable by contact only, and is usually carried from one cow to another by the hands of the milkers; hence being usually found on the udder or teats of milch cows. Since Jenner's time many theories have been advanced as to the exact nature of this disease in cattle, and at the present day the subject is still in dispute. It is now, however, generally conceded that if cow-pox is a distinct disease, originating only with the cow, the eruptive disease produced in this animal either by inoculation of small-pox virus from man or of "grease" from the horse is, at least in all essential respects, a disease not to be distinguished from primary or idiopathic vaccinia. Guarnieri has described certain parasitic organisms, the *Cytorectes Guarnieri*, found in corneal lesions produced by the injection of vaccine lymph. This observation has been confirmed by Pfeiffer and others, but the pathogenic nature of these protozoa has not been determined.

The *vaccine virus* consists either of the liquid contained in the vesicle or of the scab resulting from the desiccation of the pustule. The former is furnished from vaccine farms, of which there are several in this

country, is then dried on ivory points, and, if kept in a cool place, retains its virtue for a week or ten days, or, possibly, longer, but should be used as fresh as possible to ensure a successful result. It is also sometimes preserved in capillary glass tubes, sealed at both ends, or between glasses, and kept in this way it is less liable to infection through uncleanness in handling. The scab from the cow is not used.

The Site.—The point usually chosen for vaccination is on the arm over the insertion of the deltoid muscle; but in girls, for cosmetic reasons, it is sometimes preferred on the leg, and the most common site is over the junction of the two heads of the gastrocnemius muscle.

Technique in Vaccination.—After the part selected has been rendered surgically clean, gently scrape the skin with an aseptic lancet or other instrument until serum begins to exude. If by too vigorous scraping blood should be drawn, it must be carefully dried with a piece of sterile cotton before the lymph is applied. Hutchins has recommended a method in vaccination of denuding the surface of the skin with a caustic in place of the lancet. A piece of cotton, as large as the spot to be denuded, is wet with liquor potassæ and laid on the skin for two or three minutes, after which the spot is wiped dry and the softened epidermis rubbed away with an ink-eraser, a piece of soft wool, or preferably a piece of sterile gauze cotton, when the vaccine is applied in the usual way. The chief advantage of this method is its painlessness.

The charged end of a point, which has been previously dipped in tepid water, is now gently rubbed over the abraded spot and the limb left exposed to the air until the lymph has been dried upon it. It may then be protected by a piece of gauze strapped on it, or by a shield.

Humanized lymph is still preferred by some, and when this is used the "arm-to-arm" vaccination is best. The lymph is taken from characteristic vaccine vesicle (from the fifth to the seventh day of its development) of a healthy child and applied directly to the arm of another. The virus may be dried and preserved for use as in the case of bovine virus.

The *scab* resulting from a vaccine vesicle on a healthy child was formerly quite generally used, and it could be kept a long time without losing its virtue. It was sure in its action, and offered the advantage to the physician of being easily preserved; but it was more liable to become infected than the lymph when preserved in the usual way, and, since the vaccine farms are so conveniently located, lymph may be obtained from them at any time without delay.

The possible danger of conveying syphilis or other constitutional disease from one person to another by means of humanized lymph should lead to its abandonment in favor of the bovine lymph. In recent years, however, vaccine virus has been shown to be occasionally infected with tetanus, and a number of authentic cases, in which implantation of the tetanus germs at the time of vaccination occurred, are to be found in the literature.

Period of Life for Vaccination.—It is usually advised to vaccinate infants within a few weeks or months after birth; but unless small-pox is prevalent, it is best to wait until the latter part of the second or the beginning of the third year, as the child has then passed through its teething period and will be better able to resist the effects (slight though they may be) consequent upon vaccination. If an epidemic be prevailing,

vaccination should be performed during the first week or even the first day after birth; and pregnant women should receive prompt vaccination at any period of gestation if exposed to small-pox.

Time for Revaccination.—To ensure the individual against infection he should be revaccinated at puberty and every few years afterward, or at any time when small-pox is epidemic or is liable to become so.

Symptoms.—After vaccination no local or constitutional effects—except the slight irritation due to sacrifice—are noticed until the third day, when a *small red papule* appears. By the fifth or sixth day a *vesicle* appears. By the ninth day it is fully developed, and, like the vesicle of variola, is filled with colorless lymph, is umbilicated, multi-ocular, and has a distinctly inflamed areola of deep red color, accompanied by heat, itching, and tenderness. By the tenth day this may extend an inch or two from the vesicle. Quite frequently the axillary or inguinal glands (depending upon the location of vaccination) are swollen and tender, and in a tubercular child they may go on to suppuration. After the tenth day all these symptoms gradually decline; the *pustule* dries up, and then forms a brown scab which is usually detached in the third or fourth week, leaving a permanent cicatrix.

Complications.—Occasionally one or more additional vesicles are formed at a little distance from the point of inoculation, and, rarely, there is a general vesicular eruption, due to absorption of the lymph. An *erythematous rash* about the sixth day is not uncommon. *Erysipelas* may occur as a complication, and, if it is prevalent in the house, vaccination should, as a rule, not be performed. Among other rare complications are tetanus (*vide* p. 313) and the hemorrhagic diathesis.

An ulcer may form which may be weeks in healing. *Eczema* and other skin-affections are usually aggravated during the course of vaccination, and it is possible for *syphilis* to be inoculated with the vaccine virus. Any of these complications call for the usual treatment.

VARICELLA.

(*Chicken-pox.*)

Definition.—An acute, contagious disease, characterized by a cutaneous eruption of papules, passing into vesicles and pustules; also by slight fever and mild constitutional symptoms. For a long time it was confounded with varioloid, but its distinct character has now been recognized for many years. Complications and sequelæ are infrequent.

Etiology.—It has been shown recently by numerous observers that the virus is not transmitted by the inoculation of the vesicle contents. The specific poison has not been satisfactorily isolated, although it is suspected that certain protozoa are the direct cause, but, as in the case of vaccinia and small-pox, positive proof is wanting. Varicella may be transmitted by exposure to another case or possibly through the medium of a third person, the school and asylum being the most frequent points of its origin. It affects children of all ages, and usually one attack is protective. Doty and others have observed varicella in the adult. It closely resembles measles in its contagiousness.

Symptoms.—The *incubation* period is uniformly from fourteen to sixteen days. If there be a prodromal stage of the disease, certainly in the vast majority of cases it cannot be recognized, though a slight *fever* and general indisposition may be noticed for twenty-four hours before the appearance of the eruption. In many cases the *eruption* is the first symptom. This occurs in the form of small reddish puncta, from which rapidly develop rosy-colored maculations, and these become densely distended, transparent, or slightly yellowish vesicles of the average size of a split pea. The eruption *appears first* upon the upper part of the body, the chest and back, neck, scalp, and face (on the latter quite sparingly), and always upon the hairy scalp. Frequently the *vesicles* form on the mucous surface of the lips, inside the cheeks, on the tongue, palate, conjunctivæ, and in the progenital regions of both sexes. At times the glands of the throat become slightly enlarged and painful, the vesicles are superficial, the child has the appearance of having received a shower of boiling water, and the firm papule which precedes the variolous rash is altogether wanting. The vesicles are at first transparent, and their contents plainly show through their translucent roof-wall which is composed only of the stratum corneum of the epidermis. The contents of the vesicles become lactescent, and gradually seropurulent. The *areola* is most distinct when the vesicle is fully formed and fades as the latter dries. Desiccation begins at the apex of the vesicles. *Crusts* form, which drop off in from five to twenty days, depending upon the depth to which the skin has been involved. On the trunk, as a rule, no mark is left, but after the more severe attacks, when the true skin has been involved, scars remain, and frequently there is quite deep *pitting*. The marks are usually on the face when the skin has been unprotected. On the hands and feet the vesicles appear without having been preceded by a papule, and sometimes there is no areola, each vesicle resembling a drop of water upon a healthy skin. *Pustules* may develop in consequence of irritation or infection, as the result of scratching, or in feeble or poorly nourished children, and in unhealthy children deep ulceration may occur, lasting for weeks. In rare cases there may be necrotic inflammation about the site of the pox (*varicella gangrænosa*).

In *mild cases* only ten, twenty, or thirty spots may be found on the body, but in severe cases the skin may be almost covered in certain regions. The eruption, however, is never confluent. The *temperature* is highest on the second or third day, when the eruption is appearing. In mild, uncomplicated cases the thermometer registers 101° or 102° F. (38.8° C.) for two or three days at most, but in severe cases the temperature may be as high as 104° F. (40° C.). This is usually due to broken health prior to the acute illness. The temperature falls *gradually* as the rash fades, and presents a temperature-curve similar to that of measles.

There is usually neither coryza, cough, vomiting, nor diarrhea.

Complications.—*Erysipelas* occasionally acts as a serious complication in delicate children. It may develop about the pocks, particularly when they are deep and associated with some ulceration, and scratching with unclean fingers is its prime causal factor.

Adenitis, mild and isolated, and *suppuration* with abscesses in the deeper cellular tissue are occasionally seen.

Nephritis is infrequent, but may occur in unhygienic surroundings or

in carelessly managed cases. L. Ceof¹ has collected 40 cases of nephritis complicating varicella.

Varicella is also quite frequently complicated with other infectious diseases, and varicella, scarlet fever, and measles have been seen curiously blended in epidemic form. Ceof has reviewed the literature and found 40 cases of scarlatiniform eruption occurring in varicella. Varicella and measles, however, are more commonly associated.

The **diagnosis** of varicella offers no special difficulties. The eruption comes out slowly and in crops, so that papules, vesicles, and crusts may be seen upon the skin in close proximity. Again, it should be noted that the umbilication is due only to the fact that the drying up of the vesicle begins at the center. Varicella is distinguished from *urticaria* by the presence of fever, and from *eczema pustulosum* by the mild febrile symptoms of the latter, the discreteness of its pustular lesions, the absence of itching and of infiltration of the skin in patches, and by its tendency to symmetric development.

Variola and *varioid* of infants are to be distinguished from varicella by the prodromal symptoms, and by the greater rise of temperature, though the distinction between mild varioid and severe varicella will always tax to the utmost the skill of the keenest diagnostician (*vide* table, p. 195). The sooner it is understood that intermediate forms are likely to occur, which cannot be positively assigned to one or the other category, the better it will be for both the profession and the laity.

The **prognosis** in private practice is always favorable. Only in the slums or in hospital cases complicated by erysipelas, adenitis, or nephritis may grave results be anticipated. The milder cases may, however, leave slight monuments of their existence in the form of one or more depressed cicatrices which may mar an otherwise beautiful face.

Treatment.—Isolation should be enforced in schools and in all institutions containing many young children. In private houses, unless the younger children are delicate, quarantine is unnecessary. The disease may be transmitted to others as long as the crusts are present, and hence isolation should be maintained until they have fallen off. In most cases constitutional symptoms of the disease are so mild as to require no treatment. It is best at the outset to place the child in bed for a few days, and sponge daily with warm carbolized water; the local itching may be allayed by sponging with a weak solution of carbolic acid or by the use of carbolized vaselin. When the crusts have formed, especially on the face, an ointment of zinc oxid containing ichthyol (2 per cent.) should be applied, and care should be exercised to keep the skin clean and to prevent scratching. In all cases the urine should invariably be examined several times during and following the attack.

SCARLET FEVER.

(Scarlet Rash; Scarlatina.)

Definition.—Scarlet fever, or scarlatina, is a self-limiting, acute, contagious disease, characterized by vomiting, fever (more or less typical), angina, and in twelve or twenty-four hours by a diffuse, punctiform, scar-

¹ *Arch. de Med. des Enf.*, Feb., 1901.

let eruption, followed by membranous desquamation and, frequently, by nephritis. It is a disease of childhood, but may occur at any time of life.

Scarlatina is a widespread disease, though perhaps less universal than measles. It is endemic in all the large cities of the globe, and at intervals the cases multiply into more or less extensive epidemics. Smaller towns and rural districts are visited, and the epidemics are usually traceable to importation of scarlatinal poison, so that it may be stated that they never originate *de novo*.

Pathology.—There are no pathognomonic changes. When death occurs early the chief lesions are presented by the throat, while in addition engorgement of the viscera is noted, especially of the brain. The exanthem is rarely visible. In malignant types, however, in which the eruption is not seen during life, it makes its appearance rarely after death, and this aids in establishing the nature of the affection.

When death occurs at an advanced stage the lesions are those either of nephritis (with dropsy), or of septicopyemia, or of inflammation of one or more of the serous surfaces (pleurisy, pericarditis, endocarditis, meningitis, etc.). Additional changes in the various viscera are, for the most part, identical with those met with in other acute infective diseases, and hence need not be described here. The blood is dark, fluid, and coagulates feebly, owing to a decrease in its fibrin factors.

Among other lesions which are more or less peculiar to the disease are (a) The *eruption*, which is a dermatitis of very mild grade. J. F. Schamberg¹ points out that the discrete vesicles sometimes seen originate in the hair-follicles or in the deeper layers of the *rete*, and contain a turbid leukocytic fluid. (b) *Scarlatinal angina*, which in its mildest form usually presents more or less hyperemia and a slight swelling of the mucosa of the tonsils, soft palate, and pharynx. In the severer grades the inflammation is phlegmonous (*scarlatina anginosa*), and sometimes terminates in ulceration. There is great swelling (especially of the tonsils), and the formation of abscesses is common. Extension of the purulent inflammation to the connective tissue of the neck produces marked induration, and more or less extensive abscesses may take place. Gangrene sometimes supervenes. (c) In certain epidemics a *membranous exudate* accompanies the *scarlatinal angina*, and this may or may not be truly diphtheritic. When it appears early it is non-diphtheritic, as a rule, and often due to the streptococcus; on the other hand, when it comes on late it often shows the presence of the Löffler bacillus. Schabad has, however, shown that bacilli taken from the throats of incipient cases of scarlet fever, although morphologically characteristic, have little or no virulence. There is also a malignant form of membranous scarlatinal angina, occasioned by a secondary streptococcal infection (Hirschfeld). (d) *The Nephritis*.—The renal lesions are included in the description of "Acute Bright's Disease."

Etiology.—The bacteriology of the affection is imperfectly known. The streptococcus pyogenes has been found in nearly all the inflammatory complications of the disease, especially scarlatinal pneumonia and angina, and some pathologists (Babés, Bergé, Klein) have held it to be the cause. Marmorek, Raskin, and Mosny, however, believe that it is an example of mixed infection, the streptococcus being merely a second-

¹ *Proc. Phila. Path. Soc.*, Jan., 1901.

any factor, and Charlton has shown it to be the cause of the unfavorable complications.

W. J. Class¹ first described an organism (*diplococcus scarlatinæ*). His researches have been confirmed by those of Gradwohl,² Jaques,³ Page,⁴ and others. The habitat of the diplococcus is not known, but it has been found in the blood, throat, epidermal scales, and urine of scarlatinal cases. The size of the organism is variable, and it stains with standard watery dyes easily, uniformly, and regularly (Gradwohl).

Class⁵ reports on his experiments to obtain an *antitoxin* for *diplococcus scarlatinæ*, in which he was successful. Sommerfield⁶ has found the constant presence of streptococci in the tissues and blood. This may be the same organism as the Class coccus.

F. A. Mallory⁷ has demonstrated the presence of protozoa (*cyclaster scarlatinæ*) in the skin in early stages of scarlet fever. They are best observed on the second day of the cutaneous rash, and usually occur within the epithelial cells, but have been observed also in the lymph spaces in the corium. The most striking form is a rosette-shaped body not unlike a similar appearance seen in the life cycle of the hematozoön of Laveran, and about one-third larger than the latter.

The *general receptivity* for scarlet fever is not so great as in certain other exanthemata (*e. g.*, small-pox, measles); hence in a household in which there are several children some are apt to escape the disease, even though all have been equally exposed.

The *virus* is probably contained in the excretions from the *throat, nose, or ear*, and in the epidermal scales thrown off from the surface of the body. It is also present in the blood of scarlatina patients.

Modes of Conveyance.—(a) The majority of the cases are produced by *contagion*, and I have observed that a single contact of a healthy child with a scarlet-fever patient suffices. The disease may also be transferred by persons who have been in the sick-room, while they themselves escape. Aaser⁸ found, out of 3800 cases, 79 had been infected by discharged hospital patients from one to five weeks after cessation of desquamation ("return cases"). The source of infection in these cases is an abnormal secretion due to some local affection of throat, nose, or ear associated with discharge. (b) It is also communicated by *fomites*, and the poison of scarlatina contained in clothing retains its infective power for months. Again, any objects (furniture, utensils, library books, toys) which the patient has handled may serve to communicate the poison. (c) Infected dairies have been known to disseminate the poison and give rise to epidemics. (d) The infection may also be air-borne, though not for any great distance. (e) Behle reports an outbreak of human scarlatina in swine; and kine are potent to transmit it to man.

Mode of Infection.—Most probably the poison is *inhaled* into the throat, where infection usually occurs; but it may gain entrance to the body through the *alimentary tract*. Infection may also take place

⁸ *Nord. Med. Arch.*, 1903, Abt. II., Anhang 51.

through the blood, as is shown by the fact that children have been born in all stages of the disease. Artificial inoculation with the blood of scarlatina patients has resulted in more or less typical forms of the complaint. *Open lesions* predispose, but whether they are essential to infection is not known.

Predisposing Causes.—(1) *Age*.—The period of chief liability is from the second to the tenth year, after which it diminishes. It is rare under the age of one year, and especially so under six months. (2) *Recent wounds*—accidental or surgical—increase the susceptibility to the peculiar poison. (3) *Women in childbed*, for the same reason as (2); but care must be exercised lest this class be confounded with septic affections. (4) *Season*.—The autumn and winter months furnish the most cases. (5) Seitz believes there is evidence of a *family predisposition*, as 371 out of 800 cases occurred in 152 families.

Immunity.—Single attacks during the life of a person form a rule to which there are rather frequent exceptions.

Clinical History.—The *incubation-period* is variable, lasting, on the average, from ten to fourteen days (McCollam). It may rarely, however, be longer, although more commonly a briefer period, three to eight days.

The *invasion* of scarlet fever is generally quite *sudden* and, as a rule, active. The child feels uncomfortable, looks stupid, complains of *sore throat* and decided nausea, and in the great majority of the cases *vomits*. The tongue is furred. If he be very young, *nervous symptoms* are prominent, and the initial symptom may be a convulsion. The *pulse*, which is a strong diagnostic factor, is rapid and hard, reaching 140 to 160 at the very onset. The *temperature* rises quickly to 104° or 105° F. (40.5° C.), and remains high.

Eruption.—Within the first twenty-four or thirty-six hours the characteristic rash appears, and is, as a rule, first seen on the neck; there is no certainty about this, however, as it may first come out on the abdomen or back of the hands or on the thighs, and not be seen on any other part of the body. Frequently it is found on the dependent portions of the trunk. At first it is slight, but perfectly characteristic, and usually takes two days to mature. In mild cases it disappears within thirty-six to forty-eight hours, and at no time is more than a very fine rash, but when typical it cannot be mistaken, especially if accompanied by the premonitory symptoms. When seen from a short distance at the end of the first twenty-four hours of its appearance the whole body (except the face) is of a uniform bright scarlet color. If we examine more closely, we find that the eruption consists of a multitude of red points (*puncta*) that correspond to the hair-follicles. These points are surrounded by zones of erythematous redness, which, joining with one another, give a generally diffuse red appearance to the whole skin. Frequently, however, the rash consists of points representing the hair-follicles without the erythema, and in rough skins the rash may be more punctiform—that is, more strictly a condition of “goose skin.” Sudamina are quite frequent. Pressure by the finger causes a pallor which at once disappears when the finger is removed. The patient's lips and chin are pale and in striking contrast with the vividly scarlet cheeks. In some cases the rash is patchy, especially on the limbs, and in these cases it may suggest measles, the patches consisting of clusters of fine papules or points with much surrounding

erythema, while normal skin is present between the patches. In severe cases the rash may be hemorrhagic in character, minute extravasations of blood taking place in the skin; this may occur even in mild attacks, and not be seen until after death, but more frequently it is seen in malignant cases. Purpuric patches are frequently found after death when even in life they do not appear. There is itching, which may be intense.

The rash is succeeded by a *desquamation* that will be extensive or slight according to the intensity of the fever. In *mild cases* the tonsils, palate, uvula, and pharynx are deeply congested, and the mucosa of the cheeks, palate, and tonsils may show the eruption. In *severer forms* the tonsils are red and inflamed, and covered with tenacious secretions, while minute yellow points corresponding to the tonsillar crypts are usually prominent. (*Vide* Malignant Scarletina.) The nasal chambers are swollen, producing a free discharge, and the deeper cervical glands at the angle of the jaw are frequently enlarged. The *tongue* is coated with a thick, dense white fur (dead epithelium), and frequently shows a dry, glazed central band. In a few days the dead epithelium is cast off, clearing the tongue, when we have a red, clean, glazed tongue with greatly enlarged fungiform papillæ, giving us the *strawberry tongue* of classical history. The eyes are frequently swollen and the conjunctivæ injected.

Sleeplessness and mild delirium often mark a typical case, suggesting a congested state of the meninges, but it is neither usual for the child to be violent nor for the delirium to continue long.

The *pulse* is usually a strong diagnostic feature, and is always hard, quick, and wiry, varying from 140 to 160; its rate is out of proportion to the temperature and the general condition of the child. *Leukocytosis* is noted; it develops early and is most marked in cases showing suppurative lesions. This leukocytosis is a true one, *i. e.*, an increase absolute and relative in the polymorphonuclear cells. With the onset of defervescence there is a constant eosinophilia (Tileston and Locke). The *temperature* in average cases reaches 104° or 105° F. (40.5° C.), and in severe forms it may touch 106° F. (41.1° C.), the nocturnal remissions being slight and defervescence gradual (*vide* Fig. 17). The *urine* is scanty, thick, and contains urates, with a small quantity of albumin.

Within one week, if no complications have occurred, the attack will have reached its height and the symptoms have begun to decline. The rash gradually fades, temperature falls, the tongue is less red, the throat less injected, and the child seems more natural. If at the end of one week the fever continues, it suggests one of the many possible complications, the most frequent of which are a throat or tonsillar ulceration, inflammation of the cervical glands, otitis, or acute nephritis (common). It must be well understood that no two cases of scarlet fever are alike.

Clinical Types.—**Mild Scarlet Fever.**—In many cases of scarlet fever all the premonitory symptoms are absent, and the rash is the only indication of the complaint. There is neither vomiting nor fever to be recognized, and no tonsillar trouble of any importance, while the rash is neither uniform nor well marked. In these cases we must be very careful not to confound the eruption with urticaria or some of the many medicinal rashes.

During house epidemics when several children are affected it frequently happens that a child has sore throat and the "strawberry

tongue" without a development of the rash. This may also occur in adults, and is the so-called *scarlatina sine eruptione*. These very slight cases of the fever may be followed by the most severe attack of nephritis.

Here may be mentioned the so-called "*fourth disease*," in which the symptoms are said to resemble both German measles and mild scarlet fever and yet to be unlike either. It is to be recollected that "the symptoms may be caused by the poisons of both these affections acting simultaneously" (Dent).

Traumatic scarlatina is that form in which infection occurs in a wound (*surgical scarlatina*). The eruption makes its appearance at the wound and then spreads over the body; it is less severe in its course than ordinary scarlatina.

Malignant Scarlet Fever.—Death occurs usually by the end of the first week in severe cases, Drs. Ashby and Wright reporting a death within the first twenty-four hours (*atactic form*). In malignant cases such as usually occur among the unhygienic and delicate, the tonsils may be

FIG. 17.—Temperature-curve of a case of scarlatina with favorable course—William C—, aged seven years.

covered by a membranous exudate, and the system quickly receive an overwhelming dose of the poison; death then results from septic causes (*anginose form*). In cases in which death occurs early a child soon becomes cyanotic, restless, or more frequently somnolent. In all these cases the temperature remains high—105° to 106° F. (41.1° C.), and very frequently 107° F. (41.6° C.). Diarrhea is frequently a troublesome factor in severe cases; coryza is very abundant; there is much

glandular swelling and cellulitis, the neck becoming enormously enlarged and hard, the skin dull and livid in color; the extremities grow cold; the heart gradually becomes irregular, losing a beat, and finally fails.

If life is sustained through such an ordeal, the tonsils slough and the lungs may eventually become the seat of a septic pneumonia. General septicemia is most likely to occur. In this condition the tonsils ulcerate, sloughing patches appear on the fauces, the glands about the neck become enlarged and doughy, and the nasal mucous membrane gives out a purulent secretion in abundance. The temperature may remit, but continues high; the urine is albuminous; pus wells from both ears; and thus the child is gradually consumed and perishes.

A third variety (*hemorrhagic*) shows at first cutaneous petechiæ which grow rapidly into large ecchymotic patches. Hemorrhages also take place from the mucous surfaces, epistaxis and hematuria being very common. Death, as a rule, follows in two or three days.

Desquamation.—By the end of the first week the rash commences to disappear, the skin is (or soon becomes) mottled, dry, and rough, and gradually the scarf skin begins to separate. This process usually begins about the neck and trunk, and frequently large flakes are detached, the whole cuticle of the hand or foot sometimes coming off in one mass like a glove. The degree and character of the desquamation bear some relation to the severity of the eruption. In some cases the hair and nails have been cast off. In many cases desquamation is prolonged to the eighth week; it is usually longest on the hands and feet.

Complications.—**Otitis.**—The inflammation may extend from the throat along the Eustachian tubes to the middle ear, and pus be formed in the tympanic cavity, making its exit by perforating the membrane. This complication may occur either during the fever or at some time during convalescence. Suppuration in the middle ear is one of the common causes of a continued high temperature after the disappearance of the rash. *Pain* in the ear may not attract our attention to this unfortunate complication; most frequently, however, the child will place its hand on the ear and shake its head, as if to get rid of some source of irritation.

Pyemia.—*Pyemia* and *abscess* of the lungs may follow, and thrombosis of the lateral sinus may occur. The *tonsils* may be the seat of deep ulceration, and the soft palate may slough and show cicatrization of the soft parts of the throat in cases which may yet recover. The *cervical glands* may become enlarged and suppurate, either during the fever or while the child is convalescent. In debilitated or strumous children this complication may be very troublesome, with the formation of deep ragged ulcers, slow to heal, and in rare cases exposing the larger blood-vessels. *Broncho- or lobar-pneumonia* may occur, and is most usual during the second week, being due to extension downward of the lesion from the throat. Pneumonia followed by *empyema* may also occur during convalescence.

Joint-affections.—(a) *Scarlatinal synovitis*, which occurs in 7 per cent. of cases, nearly always appearing from the fourth to the tenth day; in 72 per cent. of cases affecting the wrists (Marsden). Less commonly the small joints of the fingers, the elbows, the ankles, the knees, and soles of the feet may be affected. The trouble is fugitive, and seldom returns to the same joint, and is caused by the scarlatinal poison. (b)

Septic arthritis, met with in severe or fatal cases, is often associated with grave throat symptoms. In these cases the knees may be most severely affected, remaining swollen for weeks, and in unusual cases suppuration may take place and be followed by pyemia. (c) *Rheumatic synovitis*, which usually develops during convalescence. Two cases have occurred in my practice, complicated with simple acute endocarditis. Rarely tuberculous invasion of the joints occurs as a *sequel*. Here the scarlatina merely affords a predisposition to tuberculosis.

Nephritis.—No other complication of scarlet fever can equal *nephritis* in importance or interest, this condition always giving rise to anxiety in otherwise mild and hopeful cases. During the height of the fever there is commonly a transient albuminuria, and it is possible for the kidneys to escape without greater damage than occurs in other acute febrile affections. Independently of this febrile albuminuria, there are two forms of nephritis which it is important to bear in mind, though they have been frequently confounded:

(a) *Septic Nephritis*.—In severe forms of scarlet fever, when the throat symptoms include sloughing tonsils, involvement of the soft palate, and general adenitis, the urine quickly becomes loaded with albumin, but shows scarcely any blood and but few casts. No renal symptoms will be recognized, and if present they may be masked by the general condition of septicemia. There may be neither dropsy nor uremic phenomena, but the patient usually dies by the end of the second week, when a typical pyemic kidney is found containing minute abscesses. This condition of the kidney is only one part of the general pyemia, and merely illustrates the fact that this organ suffers during the course of the general inflammation.

(b) *Post-scarlatinal Nephritis*.—The kidneys are undoubtedly involved in an acute sympathetic inflammation, and at the end of the fever, more than at the beginning, are engaged in carrying off waste products of the fever itself. From the nature of the disease they are in an irritable condition and prone to take on inflammatory changes, just as the bronchial tubes and the lungs are left in a very susceptible condition following measles and whooping-cough. In this way the uriferous tubules become choked up by the desquamation that is going on inside. The *number of cases* that suffer from post-scarlatinal nephritis varies according to social conditions, the nature of the epidemic, the season of the year, the nature of the treatment received during the disease, and especially the care received throughout convalescence. Ashby and Wright fix the rate of those who suffer at 6 per cent. of hospital cases, but this is, undoubtedly, too high, since hospital cases receive excellent care during convalescence as a rule. The *usual time* for this form of nephritis to occur is from the end of the second up to the fourth week, but it usually begins very insidiously. Traces of albumin may be found for a few days before the blood and larger quantities of albumin occur, but it is often impossible to date the commencement of an attack. Usually after the fever has subsided the patient for a few days feels well, but very suddenly grows restless, is feverish at night, is thirsty, has a quick, hard pulse, and passes a small quantity of dark-colored urine. The temperature almost invariably rises again and there is no relation between the pulse and the temperature. If care has been exercised, it will be found that the urine has been gradually diminishing

for several days, and a slight puffiness about the face frequently announces the beginning of the trouble. Later the face becomes pale and puffy, while there may be edema of the feet and scrotum, and some vomiting. Under favorable treatment improvement may take place, large quantities of urine may be passed, and the child resume convalescence. The nephritic symptoms may, however, deepen until *uremia* appears, the pulse becoming slow and wiry in character, the temperature subnormal, and the tongue dry and brown. Vomiting is now a frequent occurrence; diarrhea is not unusual; nose-bleed and hemorrhages from the various mucous surfaces, and muscular twitchings may be noted, and most likely the end may be reached in a general convulsion. Fatal results, however, are more frequent from *cardiac failure* than from the uremic convulsions. The constant effect of nephritis is to raise the blood-tension, followed by dilatation of the heart. Another not unusual result is *endocarditis* or *pericarditis*, with possible embolism.

Sudden death frequently occurs during the course of nephritis. The child may be doing well, possibly sitting up in bed and playing with its toys, when an attack of dyspnea occurs; the face becomes livid, the pulse disappears, and death quickly takes place. Death in such cases is usually said to be due to edema of the lungs: the *dilated heart*, however, has been overlooked, and, while edema of the lungs is present, it is only secondary to the cardiac failure.

It is not unusual for a false membrane to form upon the *larynx*. This is not infrequently due to the streptococcus pyogenes, but the Klebs-Löffler bacillus is oftener found (Ranke found it in more than half of 92 cases. A bacterial examination should always be made, and if the *diphtherial* nature of the infection has been determined the serum-treatment should be employed at once.

Diagnosis.—A typical form of scarlet fever offers few difficulties in diagnosis. The period of incubation is short in comparison with that of any of the other exanthemata, particularly variola, measles, and varicella. The vomiting, associated with high fever, would also exclude the other eruptive diseases. The pulse in itself is most strongly diagnostic, being quick, hard and wiry, striking the finger at the rate of 140 to 180 per minute. The early sore throat and the intense hyperemia of the whole mucous membrane, associated with marked constitutional symptoms, make it easy to differentiate from measles, varicella, and variola. Leukocytosis occurs in this disease, but is not present in measles nor varicella. The punctate eruption of scarlet fever is not found in any of the other eruptive diseases (*vide* table on page 219). If a child has never had scarlatina and the characteristic symptoms are present, a rapidly growing culture (taken from the throat) of the Class coccus from such a case determines the presence of scarlet fever, while its absence excludes the disease (Jacques).

The **differential diagnosis** embraces the discrimination of those rashes that follow the use of certain drugs (quinin, belladonna, potassium bromid and iodid, chloral, etc.). The characteristic invasion-symptoms (vomiting, angina, etc.) of scarlatina are absent; also the high fever and frequent, hard pulse of the latter disease. *Drug-rashes* are seldom so vivid or diffuse as the eruption of scarlatina.

SCARLATINA.

Onset is sudden, with vomiting, angina, fever, and frequent, hard pulse.

Eruption appears first on neck, face, and chest, soon becoming diffuse.

Duration, three or four days.

Desquamation begins after eruption has faded, often one week later.

Ear and throat complications common.

Nephritis is a common sequel.

Relapses exceptional.

ACUTE EXFOLIATING DERMATITIS.

Sudden, with fever only.

Appears first on trunk.

Duration, five or six days.

Desquamation begins earlier, often before eruption has faded, and involves the hair and nails.

Absent.

Not so.

Relapses common.

The **prognosis** in regular, uncomplicated scarlet fever is almost always favorable, and, unless the treatment is unusually indifferent, the patient will recover. Severe types, however, and especially malignant scarlatina are very fatal. Complications arise that will most seriously endanger life.

The **treatment** of scarlet fever is that of the symptoms, together with an attempt at arresting the complications.

Prophylaxis.—The patient should be strictly *quarantined* in an upper room for at least eight weeks or until desquamation has been completed.

During *convalescence* hematinics are required to overcome the symptomatic anemia and debility. Preisch urges the importance of separating the convalescents from patients in the first stages, and of getting the mucosæ into a healthy condition before the patient is discharged. A competent nurse should be put in charge, and, whether a member of the family or otherwise, she should wear a washable dress, and should not mingle with the family except her clothing be changed or thoroughly disinfected. The room is to be stripped of all superfluous hangings and furniture. *Inunctions* are required as soon as desquamation commences, with a view to preventing the diffusion of the dried epidermal scales; and the best preparation for this purpose consists of cosmolin, menthol, and carbolic acid, ten grains each of the latter to one ounce of cosmolin after the plan of J. Lewis Smith. Carbolyzed water, 1 : 40, may be used to sponge the surface and may be agreeably followed by cocoa-butter. The naso-pharynx must also be kept disinfected.

The *disinfection* of the physician himself, I am sorry to state, is frequently neglected. He should generate chlorin gas by the following simple method, and allow it to permeate his clothes thoroughly before going into other families: A dram of powdered potassium chlorate is placed in a saucer, and a small quantity of hydrochloric acid added. The dish is then placed on the floor, and the physician stands over the vapor chlorid as it arises until it penetrates all his clothing. This, with the free use of the whisk and thorough hand-washing, renders him non-contagious and safe in entering any home or sick-room. Perhaps a less disagreeable method is to have in the patient's house a linen duster or surgeon's apron that has been dipped in a bichlorid solution and allowed to dry. This is slipped over the clothing before entering the sick-room, and is removed after leaving.

In the room, if the case be a severe one involving the throat, I keep the gas or an alcohol lamp burning under a small dish of water, so that steam is constantly generated. To the boiling water I frequently add carbolic acid or oil of eucalyptus; this saturates the room very pleasantly, and at the same time tends to limit the extent of the contagion.

General Management.—The sick-room should be large and well-ventilated, and should be kept at a uniform temperature (68° to 70° F.— 21.1° C.). A light flannel night-dress should be worn by the child, and the bed-clothing should be light as well. The diet should consist of milk, egg-white, and fruit-juices, and after the temperature has declined soft diet may be allowed. J. McCrae¹ insists upon twenty-one days' milk diet. A return to ordinary solid foods, especially proteids, must be made gradually during convalescence.

The evidences of heart-enfeeblement often arise and call for the judicious use of stimulants. This class of agents is remarkably well borne in this affection. To a child of four years I give one dram (4.0) of brandy or whisky every second hour, and often increase the dose as required. The preparations of ammonium, particularly the carbonate and the aromatic spirits, have also been warmly recommended. They should be administered in milk as the vehicle to prevent gastric irritation. Heart-failure is best treated by baths at 90° to 95° F. and oxygen inhalations (Ausset).

Special Treatment.—In the classical work of Thomas Watson, now over fifty years old, he hints in his treatment of scarlet fever "that, if the heat on the surface be very great and distressing, he should not recommend the cold affusion, but cold or tepid sponging would be very refreshing and beneficial." This sentiment finds its echo in most works on practical medicine at the present day. The physician must quietly but firmly insist upon the patient being most thoroughly sponged three or four times daily, according to the severity of the individual case, using carbolic water (1:60), mercuric chlorid (1:8000), salt water, or alcohol and water, at a temperature of 70° – 100° F. (21.1° – 37.7° C.). Systematic bathing in this manner and inunctions as above described protect the body from certain disastrous complications and sequelæ. The ice-cap may be combined with cool spongings. In extreme cases, with marked nervous symptoms and high temperature, the cold pack, with cold affusions applied to the head and nape of the neck, may be cautiously employed, and a description of the method of giving a cold pack may be found under the treatment of Typhoid Fever. A notable reduction of temperature may be secured from an injection of a pint or more of cool water containing 2 to 10 grains, according to the age of the patient, of sulphocarbonate of soda per rectum (de Voe). To eliminate the toxins, the baths should be aided by the administration of large quantities of water, and the bowels should be kept freely open.

In regard to the use of *internal antipyretics*, I prefer phenacetin for older children, combined with quinin in capsules. Acetanilid is better for younger children, and I generally give one-third as many grains as there are years in the child's life. When medicine can be exhibited in the form of capsules, I always prefer to combine it with quinin or strychnin to overcome the tendency to depression. Phenacetin and acetanilid act successfully in controlling the nervous element, relieving headache and fever, promoting diaphoresis, and inducing refreshing sleep. Acetanilid is much more prompt in its action than phenacetin, but its effects are not so lasting. These agents are rarely required, and are not comparable in their good effects to hydrotherapy.

Internal Antiseptics.—Those remedies that are purely antiseptic, administered internally, have not given proof of their utility as yet.

¹ *Montreal Medical Jour.*, Sept., 1908.

The sulphocarbolates of zinc and of sodium, on account of their breaking up in the system and liberating carbolic acid, cannot be used in a sufficiently large dose to meet with success. The syrup of phenic acid is used by many physicians. Marmorek, and later Charlton, has used his *antistreptococcic serum* extensively, and, although it does not act as a specific, it prevents the serious complications and invariably renders the attack mild. Moser of Vienna has discovered a new serum which has given good results in a series of 400 cases.

The care of the *nose and throat*, and eventually of the *ears* will require all the skill of the medical attendant, and by commencing early in the case to give careful and constant attention to these parts we may prevent much trouble and danger later on. The attendant should use a small atomizer filled with warm water containing sodium bicarbonate (gr. xv-3j—0.975-32.0). If decided inflammation should occur, a solution of hydrogen peroxid and cold water or glycerin (1 : 5) may be used, and then be followed by an oily preparation, such as liquid albolene containing menthol (a 5 per cent. solution).

If the patient cannot tolerate an atomizer, an application of the antiseptic oil directly to the posterior nasal spaces, by means of an aluminum applicator, may be made. Faithful attention to the removal and disinfection of the secretion from the nose and throat will prevent accumulation, and thus prevent regurgitation up the Eustachian tube with its associated ear-troubles. In this way diphtheria can also be prevented from gaining its full lodgement. For the appropriate treatment of this complication the reader is referred to the treatment of Diphtheria. It has been shown that the return cases (after return from hospital) are caused by the discharges from the nasal and aural passages. If pain in the ear should indicate the extension of the trouble up the Eustachian tube, we must redouble our efforts, even though the desquamation within the tube itself may be quite beyond the reach of our detergent wash.

The external auditory canal may become blocked by desquamating epithelium, and this must be removed by gentle sponging. If the tension of the ear-drum becomes very great, it must be punctured. The method of dropping laudanum and sweet oil in the ear is objectionable, as it serves as a nidus for a collection of dust, dirt, and dead epidermis.

Moser's antistreptococcic serum has been employed with doubtful results, but it should be used in streptococcic pseudomembranous affections.

Scarlatinal synovitis I have encountered in but a small proportion of cases, and then it was of a transient character. I am inclined to attribute this fortunate result to the faithful use of daily bathing and inunctions, long continued and at least until after completion of desquamation. Widowitz recommends the administration of from 1 to 8 gr. (0.06-0.5 gr.) of hemethylamin (urotropin) to prevent nephritis. Preisich administered the drug in 600 cases, nephritis occurring in 9.16 per cent., as against 13.6 per cent. of the cases in which the remedy was not used.

The specific poison of scarlet fever is peculiarly obnoxious to the kidneys, and is largely eliminated through them; and upon this fact hinges the scientific part of the treatment of this disease. Free bathing has the happy effect of vicariously eliminating the poison in a measure at least. In post-scarlatinal uremia venesection supplemented by saline infusion produces excellent results. (For the treatment of nephritis, see Diseases of the Kidneys, p. 1021).

"FOURTH DISEASE."

(Duke's Disease.)

This complaint was first described by Clement Duke¹ in 1900. The so-called "fourth disease" resembles both German measles and mild scarlatina. The *etiology* is obscure. The incubation period is from one to three weeks, and the time of transmissibility ranges from two to three weeks. *Prodromata* are often absent, though a slight febrile movement may precede the eruption by from six to twenty-four hours.

Cotton states that catarrhal symptoms of the faucial, oral, or ocular mucosa may rarely be present. Usually the postcervical and occipital lymph-nodes are palpable early in the attack. The *eruption*, which resembles that of scarlatina, appears first on the face or neck and spreads downward, quickly covering the trunk and portions of the extremities. Itching is absent, and the rash fades rapidly after two or three days without stain.

A fine, branny desquamation follows the disappearance of the eruption. The pulse is accelerated in proportion to the febrile movement, which is marked, but lasts only two or three days. Complications are rare, while sequelæ almost never occur.

The *discrimination* of Duke's disease from scarlatina is made with readiness by noting the absence of vomiting, of a pulse-rate out of proportion to the fever, the strawberry tongue, lamellar desquamation, and of the characteristic oronasal pallor. In *rubella* the rash is light in color and presents patches of irregular shape (*vide* p. 221). Corlett and Cole² state that aberrant forms of scarlatina should not be regarded as distinct affections, and that the consensus of opinion does not substantiate the claim for a fourth disease.

The *prognosis* is favorable and *treatment* that of mild scarlatina.

MEASLES.

Definition.—An acute contagious disease, characterized by an initial coryza, general catarrhal symptoms, fever in the earlier stage, followed by a peculiar papular eruption on the face and body.

Pathology.—In uncomplicated measles we have no pathologic lesions. The only post-mortem changes found, as a rule, are those of catarrhal pneumonia and acute nephritis. All the internal organs are gorged with blood, and minute hemorrhages are found on their surfaces. The skin presents the following histologic lesions: focal necrosis, with the formation of small vesicles, isolated necrotic epithelia, diffuse perinuclear vacuolation of cells of the epidermis and of the dermal glandular structures, with congestion, edema, swelling, proliferation of the endothelial cells, and a moderate increase of the large round-cells (Ewing).

Etiology.—Measles occurs in epidemics, although sporadic cases are common in the larger cities. There is an epidemic prevalence in large centers of population every eighteen months or two years, but the different epidemics vary in their extent and fatality. It generally happens that when once the disease enters a home, street, or small court, scarcely any

¹ *Lancet*, July 14, 1900.

² *Jour. Amer. Med. Assoc.*, July 16, 1910.

one escapes who has not been protected by a previous attack. The susceptibility to measles in children is very great, except in the newborn, who seldom contract the disease. Biedert¹ found that only 14 per cent. of unprotected children escaped. In the Faroë Islands, under similar conditions, only 1 per cent. escaped (Madsen, Pannum). There is the same experience in schools and hospitals. The epidemics occur mostly in the fall and winter, yet the season has little influence. The poison is conveyed principally by *contagion*, less commonly by *fomites*. It is probably most contagious during the initial catarrhal stage.

Bacteriology.—Micrococci, *e. g.*, *streptococci*, are found in the secretions of the respiratory tract, but they have not been proved to be specific.

Czajkowski² described motile bacilli, 2.5 to 5 micromillimeters in length, which did not color by Gram's method. They grew on glycerin-agar, bouillon, and blood-serum. Schottelius³ found the *Staphylococcus pyogenes aureus* frequently in 40 cases of measles conjunctivitis, while in 40 fatal or very severe cases he found the streptococcus in 50 per cent. in the lungs and spleen.

Immunity.—One attack of measles almost always exhausts the soil, but in exceptional instances recurrent attacks may occur.

Clinical History.—The period of incubation is from seven to fourteen days, and in inoculated cases from seven to ten days.

Catarrhal Stage.—The early symptoms are those of a cold with some fever. The child has marked coryza, watery eyes, sneezes, and has a dry, croupy cough. Frequently the symptoms are those of a catarrhal laryngitis and bronchitis the fauces and tonsils being hyperemic, with abundant secretion, and, in addition, an examination of the eyelids reveals a conjunctivitis. The patient may be acutely ill, the temperature rising several degrees in the evening, and falling slightly in the morning; the fever continues high until the rash is fully developed. The rash, consisting of one or more distinct papules, may be seen on the hard palate fully twenty-four hours before it appears on the face. A transient prodromal eruption, which may be erythematous, truly scarlatiniform or urticarial, may rarely be observed.

The eruptive stage is very characteristic, and usually makes its appearance at the end of the fourth day. The neck, face, forehead, and trunk receive the eruption in the order of mention. The whole physiognomy of the child is so characteristically altered that a well-marked case may be diagnosticated at a glance. The face is flushed; the eyes are red and watery; a short, dry cough, frequently metallic in ring, is present; and the nose and cheeks are covered with crops of dusky-red papules surrounded by a zone of erythema which sharply contrasts with the normal skin between the patches. The rash on the face is both discrete and confluent, or may be arranged at times in small crescents, and in the course of a day or two the whole trunk is invaded, but in a slighter degree. By the fifth, and seldom the sixth day, the eruption has reached its height, and commences to fade, first on the face and neck, then on the body and limbs, followed by a fine desquamation. By the seventh or eighth day the rash is nearly gone, leaving a blue,

¹ *Jahrbuch für Kinderheilkunde*, vol. xxiv., p. 94.

² *Centralblatt für Bacteriologie*, vol. xviii., Nos. 17 and 18.

³ *Münchener med. Woch.*, March 1, 1904.

mottled stain over the body. The temperature, which has reached 103° F. (39.4° C.) or even 105° F. (50.5° C.), falls when the rash is fully established—i. e., on the fifth or sixth day—while the headache,

the severe cough, and general features also subside with the fever. If the temperature continues high after the rash is out, we may look for some complication, such as pneumonia or acute nephritis (*vide* Fig. 18).

An eruption first described by H. Koplik also occurs on the buccal and labial mucous membrane; it appears "as long as twenty-four hours, forty-eight hours, and even three to five days before the appearance of the skin exanthem." It is present before the signs of conjunctivitis appear, and when little or no fever is present. It was found in fifty-two consecutive patients in Koplik's clinic.

FIG. 18.—Temperature-curve of a case of measles.

This eruption consists of small, irregular spots of a bright red color, and in the center of each red spot is the interesting sign which Koplik has described, a minute, bluish-white speck. To see the latter requires a strong, glaring daylight, and they must be looked for by everting the mucous membrane of the lips and that of the cheeks. The spots may be few, and again they may be quite numerous. Widoweiz¹ and Cotter² fail to find the spots in about 10 per cent. of the cases, while Lepit³ in an analysis of 327 cases, found them almost always present. Among recent writers, J. L. Hirst, C. C. Ross, and Rolly attach great value to Koplik's sign in the diagnosis. By recognizing this sign, measles patients may be early quarantined and institutional epidemics checked.

Complications.—In some epidemics the character of the disease is very severe, being marked by high fever (105° to 106° F.—40° to 41° C.), a dry, brown tongue, delirium and convulsions, and feeble heart-action, due to the intense hyperemia of internal organs—lungs, brain, kidneys, etc. The eruption may be petechial—*hemorrhagic measles*.

The main complications are presented by the lungs. The accompanying bronchitis tends to extend to the bronchioles, causing *bronchopneumonia*. The latter occurred in 50 among 457 cases, 11.8 per cent. (Landis). The extent and seriousness of this complication are largely dependent upon the degree of the previous debility. *Lobar pneumonia* is rare.

Catarrhal or *membranous laryngitis* is frequent in the pre-eruptive stage or as a sequela. Quite rarely edema of the glottis occurs. *Ophthalmia* may occur in anemic and strumous children if strict eye-toilet

¹ Wiener klin. Woch., 1899, No. 37.

² Archives of Pediatrics, Dec., 1900.

³ Med. Mod., 1899, No. 76; Rev. Mens. des Mal. de l'Enf., July, 1900.

is not enforced. *Glandular involvement* may take place in the cervical glands. *Otitis* is frequent during desquamation, suppuration taking place in the middle ear and *meningitis* is rarely observed. This may be avoided, however, by cleansing the post-nasal spaces frequently during desquamation. *Cancrum oris* and *noma pudendi* may also appear as complications of the disease. *Diarrhea* is frequent at the end of the eruptive period and as a sequela.

The health of the child often remains impaired for a long time after an attack of the measles: it is at this period that whooping-cough, diphtheria, nephritis, and, later on, *acute tuberculosis*, may arise. *Tuberculosis* very frequently gains entrance into the system from the existence of enlarged and cheesy bronchial and mediastinal glands. Biehler found pyelitis or pyelonephritis in 9 out of 147 cases. Nervous sequelæ rarely occur (hemiplegia, paraplegia). Certain eruptive diseases are rarely *concurrent*, as scarlet fever, variola, chicken-pox, and rubella. The cutaneous tuberculin reaction is absent for about one week in measles (von Pirquet).

Diagnosis.—Epidemics may be characterized by irregular forms of the disease, and the diagnosis of sporadic cases is often very difficult. We cannot recognize it by its dermal lesions, but by the prodromal symptoms, by the fall of temperature after the eruption is well out (differing here from scarlet fever), and by the character of the pulse, tongue, and desquamation. Koplik's early sign is usually present and is distinctive. The premonitory lymphopenia and, to a less degree, the leukopenia help in making an early diagnosis (Hecker). A feverish period of four days, associated with catarrhal symptoms of the eyes, nose, and upper air-passages, a few papules on the hard palate, followed within twenty-four hours by a papular efflorescence on the face, will differentiate the disease from *variola*, *varicella*, *scarlet fever*, and *rubella*.

The accompanying table from Rotch will aid the discrimination:

| | MEASLES. | VARIOLA. | VARICELLA. | SCARLET FEVER. | RUBELLA. |
|------------------------------------|---------------|--|---------------|-------------------------------|--------------|
| Incubation . . . | 10 days. | 12 days. | 17 days. | 4 days. | 21 days. |
| Prodromata . . . | 3 days. | 3 days. | A few hours. | 2 days. | A few hours. |
| Efflorescence . . | Papules. | Macules. Papules. Vesicles. Pustules. | Vesicles. | Erythema. | Papules. |
| Desquamation . | Furfuraceous. | Large crusts. | Small crusts. | Lamellar. | |
| Complications and sequelæ . . . | Eye and Lung. | Larynx. Lungs. | | Kidney, ear, and heart. | |

The mortality differs according to the surroundings of the patient. In healthy children under favorable environment the mortality is practically *nil*, while in tuberculous and wasted children it is very large, this being especially due to complications and sequelæ. Infants may be born with the rash on them.¹ The disease is quite fatal when it follows other acute infections (*e. g.*, scarlatina).

Treatment.—Measles is a self-limited disease, and we are unable to shorten its duration, nor is there any means of producing immunity from the attack. The treatment is necessarily symptomatic; hence our efforts should be directed toward protecting the various organs that are most likely to become involved by complications, remembering at the same

¹ *Hem. Med. Chronicle*, May, 1890; *Brit. Med. Journal*, vol. i., p. 612, 1890.

time that the nose, ears, eyes, and throat are involved during the feverish stage, and that the skin is in a very susceptible condition.

The patient should be placed in a large, dark, well-ventilated room, with a uniform temperature between 68° and 70° F. (21.1° C.). He should remain in bed until the temperature has been normal for one week, and until the efflorescence has nearly faded and the desquamation is almost complete. The diet during the period of fever should be milk, bread, and light soups. Near the end of desquamation, if all symptoms are favorable, a more generous dietary may be allowed.

The bronchial cough, which may be very troublesome during the first few days, can be readily relieved by some simple expectorant and fever mixture, as—

Sig. 3ss-3j every two or three hours, according to the age and condition of the patient.

For the coryza I have found that atomizing the nares with some oily vehicle (oleum petrolatum album, etc.) is advantageous.

The skin is in a state of great irritation, and from the very commencement of the disease until the end of desquamation a daily warm bath (95° to 100° F.—35° to 37.7° C.) should be given the patient, and, after drying the body, cocoa-butter thoroughly rubbed over the entire surface. The child should live in an equable temperature for at least three weeks. For months he should be protected from sudden atmospheric changes in order to avoid general respiratory troubles. If he be predisposed to tuberculosis, cod-liver oil and creosote should be prescribed for a period of two months or more.

Chatinière has suggested the treatment of measles by red light, simply hanging red curtains over the windows and other sources of light, and exposing the patient to these rays.

RUBELLA.

(*Rötheln*; *Rubeola Notha*; *German Measles*; *French Measles*).

Definition.—An acute contagious disease. It has no prodromal stage, and is characterized by slight fever, enlargement of the post-cervical glands, and an efflorescence upon the skin.

Etiology.—Rubella was not distinguished from measles and scarlet fever until about the middle of the eighteenth century. Since then considerable controversy has arisen at different times as to its nature, the theory being at one time strongly advanced that it was a combination

of these two diseases, as many of the milder cases have symptoms common to both. That there is a difference, however, in the character and course of these diseases has been proved beyond doubt to careful observers by the facts that rubella occurs independently of either measles or scarlet fever; that contagion from this disease produces a similar disease; that one attack affords immunity to subsequent seizures (although out of a total of 719 cases, second attacks were seen in 2.5 per cent.—To-beitz); and that its onset and clinical course are characteristic.

Rubella may occur epidemically or sporadically. Although of undoubted microbic origin, the specific organism has not been isolated.

In hospitals or where persons are crowded and living under unhygienic circumstances the disease is very *contagious*, though probably less so than measles, and the epidemic will be quite general; but in family practice it is but slightly so, and the epidemics are limited, often being confined to a single household and attacking perhaps but one or two of the family. As compared with measles, the incidence shows a larger percentage of adults. As stated by Edwards, it is spread by the *cutaneous exhalations, breath, fomites, and clothing*, and is probably contagious from the period of incubation until far into convalescence.

Clinical History.—The incubation stage lasts from ten to sixteen days, though this period may vary and the disease appear three or four days after exposure. On the other hand, cases have been reported in which it was as long as twenty-five days. As a rule, the period of incubation is longer perhaps than in measles. The *stage of invasion* covers from one to three days.

For a period of a few days before the rash appears there may be noticed chilliness, pains in different parts of the body, a dull, heavy feeling, perhaps feverishness, sore throat, enlarged tonsils, and a slight bronchitis. Enlargement and induration of the postcervical glands is constant, while the anterior are also commonly enlarged.

Just before, or with the appearance of, the rash there is a rise in *temperature* to 99° or 100° F. (37.7° C.), or in severe cases as high as 103° F. (39.4° C.) or more. Again, the invasion symptoms may be absent or so mild as to escape notice, and the first sign of infection be the appearance of a *rash* which first shows itself on the face and extends downward over the body. In some cases the eruption does not follow the regular course, and is confined to one part of the body, and cases have been reported in which it only appeared on the roof of the mouth or on the tonsils. In other instances every part of the body, including the palms of the hands and the soles of the feet, may be covered.

The eruption consists of *papules*, is multiform, confluent, and of a pale or rosy-red color. The patches do not assume any regular shape or form, and the skin between them may become hyperemic and cause itching. The rash reaches its height on different parts of the body in succession, fading in one part while appearing in another. Its duration is from two to five days, and possibly longer in some cases.

A slight *desquamation* usually occurs, and a slight pigmentation of brownish color after the rash fades is frequently noticed, disappearing after a few days. The *temperature-curve* is variable, but as a rule it remains between 100° F. (37.7° C.) and 102° F. (38.8° C.) while the eruption is present. As mentioned above, sore throat is nearly always

present, with enlarged tonsils, a dry cough, and bronchitis. The glandular enlargement will also continue with the rash, and in severe cases the axillary and inguinal glands may become involved. The pulse varies with the temperature and respiration. Vomiting has been noticed as occurring during the eruption in severe cases.

After a period varying from three days to a week, with the disappearance of the rash, convalescence begins and the child rapidly regains its former health, and the whole course of the disease may be so mild that the patient cannot be persuaded to remain in bed.

Complications.—The most common are affections of the *respiratory tract* (pneumonia or severe bronchitis), and in some cases we have a *gastro-intestinal catarrh* of a troublesome character. *Diphtheria* or other contagious diseases may occur. A *relapse* is not uncommon, and may be as severe as the initial attack.

Diagnosis.—Rubella may be distinguished from *measles* by its less severe onset and course, by the absence of coryza, severe bronchitis, high fever, Koplik's spots and complications, by the lighter color, shorter duration, and more diffuse character of its rash, and the irregular shape which the patches assume. The presence or absence of an epidemic is an important factor in the diagnosis, and in cases occurring when there is no epidemic the diagnosis between this disease and measles of a mild type is difficult if not altogether impossible.

From typical *scarlatina* the diagnosis offers no difficulty. The absence of its initial vomiting, the strawberry tongue, the character of the rash (which in scarlet fever is erythematous), and the shorter duration and milder course of rubella, all render the diagnosis easy.

| RUBELLA. | ERYTHEMA. | URTICARIA. |
|---------------------------------|------------------------|-----------------------------|
| Occurs first on the face. | On the hands and feet. | In wheals on arms and legs. |
| Enlargement of cervical glands. | No enlargement. | No enlargement. |
| At first no itching. | Burning pain. | Intense itching. |
| Contagious. | Not contagious. | Not contagious. |
| Microbic origin. | Reflex origin. | Gastric origin. |

The **prognosis** in uncomplicated cases is invariably good but when the surroundings are unhygienic, or in cases in which the child has been delicate previously, it is more serious. Complications, especially pneumonia or diphtheria, may prove fatal, and in some cases the mortality reported has been as high as 9 per cent.

Treatment.—The treatment is simple and principally symptomatic. A mild cough-mixture, such as is recommended in measles for the bronchitis, nutritious but easily digested food, and medicine to regulate the bowels when necessary, fulfil all the indications for internal medication. As in measles, cool sponging should be resorted to before and during the rash; and, when the fever is high, a cool tub-bath, where practicable, will be found to reduce the temperature, quiet the patient, and hasten the appearance of the eruption. During convalescence, if the child does not rapidly regain his appetite and strength, tonics, such as tincture of *nux vomica* and syrup of hydriodic acid, are indicated.

The complications are to be treated as they arise, but the sponging should not be discontinued until the temperature becomes normal.

WHOOPIING-COUGH.

(Pertussis ; Tussis Convulsiva ; Keuchhusten.)

Definition.—Whooping-cough is a highly contagious disease, characterized by a catarrhal inflammation of the respiratory tract, associated with a peculiar spasmodic cough, ending in a whooping inspiration.

Pathology.—There is no lesion that can be considered characteristic of whooping-cough, and none around which all the symptoms and complicating conditions are grouped. In the beginning there is catarrh of the nasopharynx, and this may be the only change coincident with the development of the characteristic cough. In advancing cases this nasopharyngeal catarrh becomes generalized by extension to the lachrymal ducts, the conjunctivæ, the Eustachian tube and the middle ear, to the glottis, trachea, large and small bronchi, and the air-vesicles. The more decided pulmonary lesions—emphysema, pulmonary collapse, pulmonary congestion and edema, and bronchopneumonia—are advanced pathologic conditions accompanying the later stages (W. W. Johnston).

The *postmortem* table does not give as much information as to the pathology except as to the sequences of the disease. In the early stages swelling and redness of the respiratory and digestive tracts will be found, together with a large quantity of viscid mucus.

Etiology.—The disease occurs in *epidemics*, yet occasionally may appear *sporadically*. Pertussis seems to have a tendency to occur in epidemics every two years, although in large cities the disease is generally endemic. Pertussis is directly *contagious*, though scarcely so in houses and school-rooms, unless it be for those of a specially susceptible nature. It is possible, however, for the disease to be propagated in schools, though not to the same extent as measles and scarlet fever. It seems that a more decided and prolonged personal contact must be made, as with members of a family, to ensure transmission. One close exposure in a susceptible child may be sufficient to ensure an attack. The germs seem to be located at first in the secretions of the respiratory tract, and are thus disseminated through the air, the disease being most highly contagious, therefore, during the paroxysms of coughing. Goodhart reports a case in which a third party conveyed the disease from one child to another, thus suggesting that the contagion is ponderable.

Predisposing Causes.—The influence of the *seasons* does not seem to have any effect, though perhaps fall and spring are the more frequent periods; the station in life, whether hygienic or unhygienic, does not modify the disease. *Bad ventilation*, however, may propagate the disorder, and cause additional cases by favoring the increase of germs in the immediate surroundings. The *previous condition of health*, especially of the respiratory mucous membrane, seems to possess some predisposing influence, weak, delicate children, with an irritable digestive tube associated with a catarrhal state of the respiratory passages, more readily contracting whooping-cough than those in robust health.

There is an intimate association between whooping-cough and *measles*; epidemics of measles are often followed by whooping-cough in the same sufferers. This is possibly due to the sensitive condition of the mucous membrane left by the measles, which is so favorable to the lodgement of the germs of pertussis; and the association of the two diseases must be more than

accidental. There exists a certain individual susceptibility, which, however, is not universal to whooping-cough, as well as to other infectious diseases.

Age exercises some influence on the development of whooping-cough, most cases occurring before the tenth year; after this time the frequency of the disease rapidly diminishes. West states that one-half of all cases develop under three years, but he must have based his knowledge upon an experience in hospitals and children's homes, as the experience of others does not sustain his statement. The disease occurs in adults but rarely, this being due partly to the fact that so many have suffered from it while young, and partly to a lessened susceptibility. It occurs frequently before the first year, and when it does it is the most fatal of all the diseases of childhood (Goodhart).

The *sexes* are about equally divided as regards susceptibility; many writers, however, seem to think that girls are more liable.

The *highway* of the contagion of whooping-cough into the system is evidently the respiratory tract, though this fact needs confirmation. Published cases of pertussis in the newborn would even seem to make its transmission possible through the fetal circulation, yet the reports are neither numerous nor satisfactory. One attack is usually protective for the rest of life, although exceptions to the rule may be found.

Nature and Bacteriology.—The true nature of whooping-cough has been thoroughly discussed, but is not, as yet, fully settled. Many writers claim it to be a simple bronchitis due to "cold," associated with a certain nervous habit or mimicry. The cough is started by the bronchial irritant and soon tends to become a habit, thus returning again and again, until it dies out in the oblivion engendered by more healthy and regulated discharges of nervous energy (Goodhart). It has been held that the disease is a lesion of either the pneumogastric, phrenic, sympathetic, or recurrent laryngeal nerves, or perhaps even of the medulla. If this ground be valid, whooping-cough is simply a neurosis. Eustace Smith says it is caused by the pressure of the enlarged tracheal and bronchial glands upon the terminal filaments of the pneumogastric nerve. Whatever the direct cause, the contagious character of whooping-cough, its appearance in epidemics, its incubating period, and the possible immunity from subsequent attacks, seem to prove beyond argument that it should be classed among purely infectious diseases.

Bacteriology.—Linnæus (to quote Dr. J. P. C. Griffith, in the *American Text-Book of Diseases of Children*) attributes pertussis to the presence in the nose of larvæ of insects. The researches of Afanassieff in 1887 have attracted much attention. This observer isolated a short bacillus, which he named the *bacillus tussis convulsivæ*, and of which he was able to obtain pure cultures upon various media. Animals inoculated upon the respiratory mucous membrane with these cultures exhibited some of the symptoms of the disease and developed catarrhal conditions of the respiratory tract, with a tendency to bronchopneumonia. These observations have been confirmed by others, and a toxin has also been reported as present in the urine of patients suffering from pertussis which is identical with that produced by Afanassieff's bacillus. Kuoloff believes that the parasite of whooping-cough is a specific micro-organism, a protozoon, and has found uniformly in the fresh sputa of patients ameboid organisms with spheric spores characterized

by concentric laminations.¹ Czaplewski and Hensel describe a short bacillus with distinctly staining rounded ends, and commonly occurring in pairs. It is found in sputum, both free and in pus-cells, increasing as the disease advances. It can be obtained in pure culture; and grows on any ordinary medium except potato. It resembles Koplik's bacillus. The latter is facultative-anaërobic. The organism is not found in the sputum during the prodromal stage.² Arnheim³ found in fatal cases of pertussis Czaplewski's pole bacteria, which he was able to cultivate and which were pathogenic to white mice. Jochmann and Krause⁴ have recently isolated a specific microbe and called it the *bacillus pertussis eppendorffii*, but their claims have not as yet received full confirmation. The careful investigation of Myer-Huni and of von Heroff indicate that the catarrhal inflammation is especially pronounced on the posterior wall of the larynx in the interarytenoid region, the so-called "cough region." Undoubtedly we have in whooping-cough an infectious catarrhal process which affects the mucous membrane controlled by the superior laryngeal nerve. Hence the value in many cases of purely local treatment.

The nature of the "whoop" has been frequently discussed to show the nervous origin of the disease, yet the infantile larynx is capable of responding to purely neutral stimuli owing to the flexible nature of the young cartilage. If we carry a young, sleeping child from a warm room out in the cool air, the same characteristic whoop may be produced.

Clinical History.—The period of incubation varies from four to fourteen days, according to the extent of catarrhal trouble in the child existing at the time. Goodhart gives several authenticated cases in which the incubation ended on the eighth day. In the beginning the symptoms are those of a slight bronchial cough, which has a tendency to be more pronounced during the night. After a few days the cough assumes an influenzal character, and at the same time it gradually grows metallic in ring and shows a laryngeal type. There is some fever present. There is a pronounced leukocytosis, with preponderance of the lymphocytes. This catarrhal or feverish stage lasts for a week or more, when it is followed by the paroxysmal stage, and these stages are divisions of the symptoms worthy of recognition, as the treatment in the first is not applicable to the second. Many authorities speak of a third stage as one of decline, which does not sharply occur, but includes the sequence of the disease. The catarrhal stage lasts about one week or ten days, during which the child is ill at ease, is feverish, and has a hoarse, dry cough. The symptoms may either be entirely laryngeal at first or bronchial, with a loss of appetite and broken rest at night. Auscultation at this time will reveal a few moist or dry râles in the larger bronchial tubes, but there is very little secretion. The cough seems to be out of proportion to the physical signs. As the catarrhal stage proceeds the cough commences to indicate its character by becoming more noisy, increasing especially at night. The physiognomy of the child commences to change, the face is swollen, the eyes suffused and watery, the under lids swollen and pink in color. This is one of the most decisive indications of the trouble, and may be recognized by a careful observer a few days before the "whoop" begins which stamps the disease and ushers in the second stage. The

⁴ *La Semaine Medicale*, Aug. 21, 1901.

commencement of the **paroxysmal stage** is quite different from the easy and more constant coughing of the first stage. If the child is in bed, the onset of a paroxysm is usually quite sudden, but if he is up and playing, there is a period of restlessness, a premonition of the coming storm similar to the aura in epilepsy, and the child may even have time to run to his mother or nurse before the paroxysm comes on. Usually the paroxysms are induced by a quick inspiration, as during drinking, eating, or crying. The first (expiratory) part is short, and followed by a short whoop; this is very quickly followed by a long series of short expiratory efforts and a second and longer whoop, when the paroxysm may cease. In some cases a third and a fourth may quickly follow, until the child is quite exhausted. The paroxysms, whether short or long, generally terminate with vomiting or eructation of a quantity of stringy mucus. Food is ejected, and in most cases a little blood is mixed with the vomited mucus.

At this stage of the disease, if at all severe, the *countenance* of the child is characteristic, and so much so that a mistake is no longer possible: the features are swollen, puffy, and dusky in color; the eyes are injected, the lids swollen and pink; the skin livid, due to a minute ecchymosis of the smaller capillaries. In many cases there will be extravasation of blood beneath the conjunctiva, due to the violence of the congestive cough. If the chest be examined at this stage, it will tell but little, provided we have no broncho-pneumonia, though a few moist râles may be found scattered through the larger tubes.

The spasmodic stage of whooping-cough has no set *duration* and varies frequently in intensity. In severe cases it may consist of twenty to forty paroxysms during the twenty-four hours. Some spasmodic coughs are not accompanied by a whoop, and the absence of this sign may be noted in very young children, as well as in those that are very ill with broncho-pneumonia. Some children vomit after a coughing spell without the whoop.

It is frequently observed that long after the spasmodic spell has come to an end the paroxysms return again and again, perhaps years afterward, with almost characteristic features, evidently acting under the stimulus of some perfectly neutral catarrh.

Complications.—In severe cases the complications may be numerous.

Epistaxis often occurs in children; *hemoptysis* when vomiting is frequent; *ulceration* of the frenum linguæ in violent coughing; *convulsions* in vigorous children; and *broncho-pneumonia*, *pleurisy*, *pericarditis*, *laryngitis*, and *hernia* in severe, prolonged coughing. Convulsions and broncho-pneumonia are alarming, and in young children a *profound stupor* may replace the convulsions. Eshner¹ states that peripheral neuritis is a rare complication of this disease. Interlobular emphysema has resulted from whooping-cough (Finch).

Sequelæ.—*Acute nephritis* frequently occurs, and is as severe as that found in scarlet fever. In a series of over 200 cases I have found the kidneys affected in 20 per cent. Knight found albuminuria in 66 out of 86 cases examined. *Emaciation* is a very important sequence of pertussis. All the viscera are liable to fatty degeneration, and nutritional changes open the door to cheesy, glandular altera-

¹ *American Medicine*, June 21, 1902.

tions, and eventually to a secondary tuberculosis. Atelectasis, by curtailing lung space, frequently brings about a general collapse, and this condition frequently explains the flattened chest found in young adults. Conversely, emphysema may be initiated by pertussis early in life. Emaciation may also be due to *mucous disease*, a chronic gastro-intestinal catarrh of long standing.

Prognosis.—Associated with its complications, pertussis is a very fatal disease, especially in children under two years of age. Dolan regards it as third in rank among the fatal diseases of England, where the death-rate per million is five thousand annually. The deaths occur chiefly among children of the poor and in bottle-fed infants.

Goodhart regards whooping-cough as the most fatal of all the diseases in children under one year of age. He places the mortality at 12 per cent., and thinks that this is not too high; his statement, however, is hardly warranted, as he includes the deaths from the many sequelæ which we cannot estimate. Ashby and Wright place the mortality at 7.6 per cent.

Differential Diagnosis.—Young infants usually do not “whoop,” but cough spasmodically. Children with *pleurisy* or *pneumonia* do not whoop, yet we diagnose whooping-cough by the preceding catarrhal fever. From *influenza* in its early stages it is most difficult to differentiate the affection. The pink under eyelid has to me been the most certain sign. When the whoop appears and during the existence of an epidemic, however, the diagnosis may be rendered certain.

The diagnostic points prior to the whooping stage, enunciated by Eustace Smith are as follows: “If a child be made to bend back the head, so that his face becomes almost horizontal, and the eyes look straight upward at the ceiling above, a venous hum, varying in intensity according to the size and position of the diseased glands, is heard with the stethoscope placed upon the upper bone of the sternum. As the chin is now slowly depressed the hum becomes less loudly audible, and ceases shortly before the head reaches its ordinary position.” It is true that we do not recognize the hum caused by the enlarged bronchial gland, but it occurs long after other symptoms are manifest.

I have for several years been able to place considerable value on the peculiar puffiness of the mucous membrane of the eyes and the swollen or edematous condition of the whole face and almost dusky color. This condition may exist for days before the catarrhal symptoms have extended throughout the respiratory mucous membrane. The cough at this stage may not be at all suggestive, but purely bronchial.

This symptom of fulness about the eyes suggests *measles*, and must be differentiated from it. As we are able to diagnosticate measles by its appearance first on the hard palate, so we may diagnosticate whooping-cough in its earliest stage by the characteristic swollen condition of the eyes and face. The diagnosis may be confirmed by leukocytosis and the presence of a sublingual ulcer.

Treatment.—The gravity of pertussis is scarcely appreciated either by the general physician or the public, and there is more criminal neglect in connection with whooping-cough than with any other disease.

Hygiene.—Throughout the whole course of the disease out-door life, as far as possible, should be encouraged, and if convenient a sojourn at the sea-shore will shorten the progress of the trouble and limit to a

great extent the number of sequelæ. Only the severe and complicated cases need to be kept in bed. It has been shown that the number of attacks is directly dependent upon the amount of CO_2 present in the atmosphere (Forcheimer). In cities the sufferer must be protected against the dust; this may be accomplished by the wearing of a veil in suitable cases.

Medicinal treatment is exceedingly unsatisfactory, although the therapeutic measures which have been advocated are boundless. The remedies most in use are the antispasmodics and the germicides.

Whooping-cough has a striking parallel in diphtheria, in that it has in its early stages a strong tendency to fasten itself upon the throat. How long this period exists we do not know to a certainty; yet there is undoubtedly a period in whooping-cough, as there is in diphtheria, long or short, in which the virus—if it could be recognized—could be destroyed and the disease terminated. To abort cases thus within two weeks is not unusual, and this explains the number of reported cures made by germicidal remedies.

I have notes of 2 recent cases in which the characteristic whoop commenced at once with the general catarrhal symptoms, and was cut short by a hydrogen-peroxid gargle. These 2 cases illustrate very clearly the fact that the germs of the disease will locate on the mucous membrane of the respiratory passages and bring about a nerve-discharge which ends in the characteristic whoop. In my treatment of this disease I find the greatest necessity for recognizing the affection early in the catarrhal stage. We must remember that the two stages are not sharply defined, and that either the one or the other may be lacking.

The drugs I have found most efficient in the catarrhal stage have been hydrogen peroxid for sterilizing the naso-pharynx, and belladonna and asafetida for the paroxysms.

To be more explicit, I will detail the methods of procedure in a family in which I have instituted my plan of thorough treatment: A child of four years attending kindergarten was brought to me with a suspicious cough. The history was given of an exposure of over two weeks prior. The child had coughed for a few days, more at night than in the daytime; was feverish during the evenings; showed slightly swollen eyelids, thus suggesting the nature of the impending trouble. I ordered hydrogen peroxid and pure glycerin in equal parts, which were well diluted and thoroughly sprayed through the naso-pharynx every four hours. The diet was light and digestible; out-door life was encouraged, except on windy days. At night the child was placed in a large, well-ventilated room, and over its cot was erected a mosquito netting, so as to prevent any unusual draught—a procedure which I have found highly beneficial. When the cough was fully established and was accompanied by eructations of stringy mucus, I commenced the exhibition of the mixture of asafetida $\frac{1}{2}$ dram (2.0) every two hours. The record of the paroxysmal stage was as follows: The first week averaged six coughing spells per day; the second week averaged ten per day; the third week, four paroxysms; and the fourth and fifth weeks averaged about two paroxysms during the twenty-four hours. When the younger brother, but eight weeks old, commenced to show evidences of the disease, I first used hydrogen peroxid as in the older brother, and immediately followed it with asafetida. The case ended favorably.

My second choice is the tincture of belladonna, exhibited in doses of one drop for every year of the child's life, the doses being rapidly increased until toxic effects are reached. Then I gradually increase the amount as tolerance of the drug seems to be established. In very young children I have obtained good results from the use of a freshly prepared belladonna plaster placed between the scapulæ, and the physiologic action of the drug seems thus to be more constantly maintained. I have gained a decided advantage by an application of a 2 per cent. cocain solution directly to the naso-pharynx in a few bad cases. This treatment, however, does not preclude the use of hydrogen peroxid, which should be continued throughout the catarrhal stage. Irrigation of the nostrils thrice daily with a 1 : 40 carbolic acid solution has proved curative in its effects. Bradt declares that local treatment of the naso-pharynx tends to arrest the syndrome.

Bromoform was resorted to in fully 20 per cent. of my cases, and was a keen disappointment. The coal-tar products, pushed to the toxic limit, modified the disease but slightly. A drug that has almost reached the rank of a specific in my hands is the following: Atropin sulph., gr. j; aqua distil., ʒj. Each drop contains $\frac{1}{480}$ gr. atropin and this dose may be increased drop by drop until the full physiologic effect of the drug has been obtained. If this effect is maintained with the onset of the paroxysmal stage, much time is saved. This outline of the drug-treatment in whooping-cough has reference solely to the catarrhal and paroxysmal stages of the disease. Kilmer has advocated a tightly placed thoracic and abdominal belt, which has yielded great satisfaction. Goodson warmly commends the use at the earliest moment of the continuous inhalation of creasote; he also advocates clearing the lungs of bronchitis as much as possible before using any special internal antispasmodic remedies.

Complications and Sequelæ.—Complications may be avoided by maintaining constantly the alkalinity of the body fluids. Sodium bicarbonate and the various alkaline waters are strongly indicated, and milk should be given in seltzer water.

Passalarqua¹ has employed diphtheria antitoxin successfully in 7 cases; it is especially indicated when bronchial or pulmonary complications exist. Diet of the simplest character and a uniformly quiet life must be maintained.

PAROTITIS.

(*Mumps; Parotiditis; Epidemic Parotitis.*)

Definition.—An acute contagious disease, characterized by an inflammation and swelling of the parotid gland, and occasionally by an involvement of the salivary glands, the testicles, and in the female the mammæ.

Pathology.—Opportunities for post-mortem examinations are rare, leaving in some doubt the pathologic course of the disease; but it probably begins as a catarrhal inflammation of the ducts, involving the

¹ *Rev. Française de Med. et de Chirurg.*, 1905, No. 11.

periglandular connective tissue. The inflammation is seldom severe enough or of such a nature as to produce suppuration.

Etiology.—Mumps is undoubtedly a constitutional or blood-disease with local manifestations. "It is a question," Goodhart says, "with mumps whether this disease shall be placed with the specific diseases or with those affecting the parts or organs with which the symptoms more particularly concern themselves."

The disease is no doubt of *microbic origin*, but the specific organism has not yet been isolated, and, while there has been some reason to believe that it is a bacillus, this has not been proved and is still doubtful. It is highly *contagious*, and at times, usually during the spring and autumn, becomes epidemic. It is communicated principally by the *breath* and *exhalations*, the greatest source of contagion being the salivary secretions. It may, however, be carried by a third person or by fomites, and is most liable to be communicated during the beginning of the attack, although the contagiousness continues until after the subsidence of the febrile symptoms. It occurs mostly among *children* and *young adults*, infants and old persons being rarely affected, while males are more liable than females. One attack usually gives *immunity* from a second attack in the same gland.

Clinical History.—The average period of *incubation* is fourteen days, but it may develop as early as ten or as late as twenty days after exposure. The *invasion* is marked by languor and a temperature from 101° to 103° F. (38.3°–39.4° C.), with possible headache and vomiting; the patient complains of pain at the angle of the jaw, and this is greatly increased if an acid (such as vinegar) is swallowed. With these symptoms is noticed a *pyriform swelling* of the parotid glands, the one on the left side usually appearing first, and the other one soon following. Occasionally cases are seen in which but one gland is involved, or the swelling may begin in both at the same time. This increases gradually until some time between the third and sixth days, involving the other salivary glands and causing marked disfigurement; the swelling fills the depression beneath the ear and extends to the cheek and neck, the most prominent part being just below, and pressing outward, the lobe of the ear. The *salivary secretions* are generally much increased, though there may be the opposite condition of marked dryness of the mouth. When the swelling has reached its height, pressure on the adjacent tissues causes a disagreeable sensation of tension, and chewing, swallowing, and even speaking, are at times painful and difficult. The *skin* over the affected part may be of a pale or of a dull-red color. Ringing in the ears and a dulling of the hearing is common. The *nervous system* may be affected, causing headache and delirium, or a low typhoid state may be present. The *duration* is about one week (six to ten days), after which time the swelling subsides, and by the tenth or twelfth day entirely disappears.

Diagnosis.—The diagnosis is easy, the nature and position of the swelling and the course of the disease being characteristic, while the fact that the tonsils are seldom involved prevents a diagnosis of acute tonsillitis.

Occasionally, however, in the course of *septic infection* or after operations, or owing to the extension of inflammation along the duct

from the mouth, the parotid gland becomes the seat of an acute inflammation at first hardly distinguishable from mumps. The existence of a possible source of infection, and the fact that the gland under these circumstances usually undergoes suppuration, should lead to the recognition of the true nature of the case.

Complications and Sequelæ.—Mumps, as a rule, runs a mild course without any serious symptoms, but occasionally complications arise. The most common of these are *orchitis* in the male, which may be followed by atrophy of the testicle; and *mastitis*, *ovaritis*, or *vulvo-vaginitis* in the female, especially after puberty. These complications appear after the subsidence of the swelling of the glands of the neck, only occasionally developing while the glands are still affected, though cases have been reported in which the disease first manifested itself by involvement of the sexual organs. This complication lengthens the course of the attack and increases the constitutional symptoms, but the rule is complete recovery. *Otitis media* sometimes occurs, and a lesion in the auditory nerve, with more or less deafness (which, unfortunately, may be permanent), has been observed. *Meningitis*, with active brain-symptoms, *facial paralysis*, *convulsions*, *albuminuria*, and *arthritis*, have all been noted in certain cases. Jacob reports a case of mumps complicated with acute pancreatitis.

Treatment.—The patient should be kept in a well-ventilated room of even temperature, and in bed if the fever is at all severe, and should be isolated from those who have not had the disease. Either hot or cold applications to the swelling will often give relief, and support to the swollen gland by means of cotton and a bandage is very comforting. Saline laxatives may be given, and aconite or some simple fever-mixture at the beginning of the attack is usually indicated. These simple measures are all that are required in an ordinary case, while complications or unusual conditions must be treated as they arise.

TUBERCULOSIS.

Definition.—A chronic (less frequently acute) infectious disease, caused by the bacillus tuberculosis. This organism produces specific lesions, taking the form either of separate nodular masses or diffuse growths, infiltrating the tissues, while aggregations of these elementary tubercles give rise to large tubercular masses. Tubercles undergo caseation and sclerosis, followed in turn by ulceration (in consequence of secondary pyogenic infection), or, more rarely, calcification.

Historic Note.—Prior to the discovery, in the early part of the nineteenth century, by Bayle and Laennec, of the tuberculous new growth as a distinctive body, this disease had been studied chiefly from a clinical point of view. At this early period the disease was believed to consist chiefly of a suppurative process, and in its observation the physician was unaided by auscultation. Later, the tubercle was recognized as a small rounded nodule without any special histologic cha-

racteristics. Villemin in 1865 performed his epoch-making experiments, and the tubercle was no longer distinguished by its anatomic characters alone. Though the theory of the infectious nature of tuberculosis had been previously advanced by Buehl and others, it was first clearly demonstrated by Villemin's beautiful inoculation-experiments upon rabbits and guinea-pigs with particles of tubercular and cheesy substances, producing the characteristic lesions of tuberculosis. It then remained for Koch to discover (in 1881) the specific cause of the most important of all human ills—the tubercle bacillus. So soon as the specificity of the disease was definitely established it became clear that the associated inflammatory processes, that were formerly believed to be primary lesions, were secondary.

Geographic Distribution.—Tuberculosis prevails in almost every quarter of the globe, but is more prevalent in certain latitudes than in others. Thus, in general terms, it may be said to prevail more extensively in warm than in cold countries. Local conditions, however, exercise a more decisive influence in engendering predisposition than mere geographic position. It is of quite frequent occurrence in all densely populated municipalities, and more especially in the overcrowded sections of the latter; this fact explains why the inhabitants of cities of the North are but little less spared than those of the cities of the South. On the other hand, residents of mountainous countries, owing to the purity of the atmosphere and the elevation, are rarely victims.

General Pathology of Tubercular Lesions.—**Distribution of the Lesions in the Body.**—Tuberculous new growths elect, most frequently, the lung, and when the disease occurs in the adult this organ is almost invariably implicated. Next in frequency follow the larynx, intestines, peritoneum, urogenital organs, and the brain. The other chief viscera of the body (spleen, liver, heart, etc., particularly the latter) are less commonly the seat of tuberculosis. In children the lesions exhibit a different distribution, the favorite seats being the lymph-glands, intestines, bones, and joints. In them the distribution corresponds pretty closely, if we except the bronchial and mesenteric glands, to that of surgical tuberculosis.

The Elementary (Nodular) Tubercle.—This may be developed in any tissue to which the tubercle bacillus has found its way, and the presence of the bacillus is its sole distinguishing feature, since apparently identical bodies are produced by other micro-organisms—*e. g.*, certain of the worms (eggs of the distoma), actinomyces, aspergillus glaucus, aspergillus funigatus, and even as a result of irritation by certain foreign bodies (podophyllum). Various forms of pseudo-tuberculosis have been described, but all are due to micro-organisms that differ from the bacillus tuberculosis. Mallassez and Vignal described a form produced by a micrococcus occurring in a zoöglea; this was confirmed by Nocard, Eberth, and others. Charrin and Rogers have described still another form, in which they found bacilli about 1μ long, actively motile, and growing freely upon ordinary media, but not growing upon glycerin and agar, and not liquefying gelatin.

The various stages in the development of a tubercle are—

(a) *Proliferation* of the fixed-tissue elements (connective tissue, endothelium of the capillaries, etc.) of the part infected, due to the local,

specific irritant action of the bacilli. These anatomic elements are transformed into epithelioid and giant cells. The epithelioid cells assume various shapes, chiefly rounded and polygonal; they have vesicular nuclei, and soon show tubercle-bacilli in their interiors. A certain proportion of the epithelioid cells, as the result of increase in their size and a repeated division of their nuclei, or by union of contiguous cells, become *giant cells*. The latter occupy the center of the tubercle, and also contain bacilli, the number of giant cells and of the bacilli being largely reciprocal. Thus, the giant cells are numerous in tubercular lymph-glands, joints, etc., in which the bacilli are relatively few; on the other hand, they are scanty in miliary tubercles, in which the bacilli are numerous—two facts supporting the view that giant cells display phagocytic action. Hektoen asserts that the giant cell is a living defensive agent.

(b) About the site of infection a *diapedesis of leukocytes* occurs in the nature of a defensive inflammatory process. At first the leukocytes are of the polynuclear variety and are quickly destroyed; but later mononuclear leukocytes (lymphocytes) appear. These latter resist the action of the bacilli, and I think their true function is a phagocytic one. The various forms of cells described are connected and surrounded by a reticular stroma "formed by the fibrillation and rarefaction of the connective-tissue matrix" (Baumgarten).

The fully-developed tubercles are small, nodular bodies whose diameters range from $\frac{1}{2}$ to 2 or 3 mm. At first they are almost transparent, but soon lose this quality in consequence of the further changes described below. They are avascular bodies, and invariably undergo degenerative changes: (a) *caseation* and (b) *sclerosis*.

(a) *Caseation*.—This implies "coagulation-necrosis"—a destructive process proceeding from the center toward the periphery of the tubercle, and the result of the local action of the bacilli or their toxins. The cells are thus transformed into a uniformly yellowish-gray structureless matter. When the foci are numerous and closely set, fusion may occur, with the production of larger or smaller homogeneous masses (cheesy pneumonia). The latter may soften, resulting in the formation of cavities: this is due, usually, to secondary pyogenic infection, causing ulceration. Less frequently the cheesy masses undergo calcification or become encapsulated, and are then practically harmless.

(b) *Sclerosis*.—Preceding and during the time that cell-destruction is going on in the center of the tubercles the protective forces of nature are asserting themselves, though too often without avail. In the first place, hyaline transformation, with conversion of the cellular elements into fibrous tissue occurs. Frequently, now, the center of the tubercle is caseous and contains bacilli, while the peripheral parts are quite hard. Here the bacilli are incarcerated (*latent tuberculosis*). The fibroid change may pervade the entire tubercle. Again, the fibroid element in the tissues immediately surrounding the tubercle may be greatly increased and form new connective tissue, and this process be followed by secondary contraction, converting the tubercle into a firm fibrous nodule. The fibroid change in its completest development is observed in tuberculosis of serous membranes.

In every case of tuberculosis there is a battle for supremacy between

the destructive forces on the one hand and the resisting, conservative forces on the other hand. As mentioned above, limitation of the tuberculous process takes place by fibrous encapsulation. In the majority of instances, however, the bacilli fall upon a receptive, favorable soil, when nature's benign curative means fail and extension occurs by the appearance of secondary tubercles in adjacent tissues. The dissemination and transportation of the bacilli are effected principally through the lymph-channels and blood-vessels, although to some extent also by the phagocytic leukocytes. Again, infection may occur by actual contact of the affected organ with neighboring parts, the disease spreading by continuity. Lastly, lesions may be propagated by the movement of organs; thus localized peritoneal tuberculosis may rarely become generalized in consequence of the peristaltic movements.

Again, fusion of minute centers of infection or of miliary tubercles results in the formation of larger nodules or areas, which lead by a process of local extension to *diffuse tuberculous infiltration* (gray infiltration of Laennec). An entire lobe may become similarly involved (tuberculous pneumonia), and "there may also be a diffuse infiltration and caseation without any special foci, a widespread tuberculous pneumonia induced by the bacilli" (Osler).

The term "gray infiltration" is misleading, since the morbid changes differ in no essential manner from those described as occurring in the miliary or nodular tubercle. Moreover, the latter also presents a grayish appearance. The apparent difference between a miliary tubercle and diffuse tubercular infiltration lies in the fact that the latter displays a clearer tendency to spread by direct extension.

Associated Inflammatory Processes.—The tubercle bacilli excite associated inflammatory processes in the organs affected, and if the tuberculous lesions run a slow course a limiting wall of true fibroid induration circumscribes the area involved. By means of this induration the natural protective forces, either temporarily or permanently, check the progress of the local lesions, and the change is strictly analogous to the sclerosis that takes place in the peripheral parts of the elementary tubercle or immediately surrounding the latter, as in tuberculosis of serous membranes. On the other hand, when the tuberculous infiltration is less tardily developed the collateral reactive inflammation may show changes similar to those of catarrhal or croupous pneumonia (*vide supra*). Examination of the sputum, to determine the nature of a mixed infection, is of little value, since the sputum may show various organisms that have not caused any real infection, and that have entered the sputum from the throat or buccal cavity.

Etiology.—The Specific Cause and its Physical Characteristics.—In 1881, Koch discovered the tubercle bacillus, which is the sole cause of the disease. The bacillus is rod-shaped, straight or somewhat bent, and slender, its length equalling about one-third or one-half of the diameter of a red blood-corpuscle (Fig. 19). Its extremities are slightly rounded, it is non-motile, and on the interior of the bacilli small colorless spots can be observed on microscopic examination; these clear spaces in the bacilli represent plasmolysis, and have nothing to do with spore-formation. Spores do not occur.

When stained the bacilli have a somewhat beaded appearance. The tubercle bacillus is one of the few varieties of bacteria that retain the anilin dye after washings with acids.

Biology.—The bacilli can be grown on culture-media, but not without difficulty, since they demand an even temperature between 98° and 100° F. (37.7° C.), or that of the human body. The best soil is blood-serum previously coagulated by heating and glycerin-agar. Over the surface of the medium gently rub tuberculous tissue, which is then allowed to remain on the surface. The growth of the bacilli requires about two weeks, when colonies appear as dry, grayish-white or grayish-brown, thin scales or masses on the surface of the culture-medium. From such cultures others may

FIG. 19.—Tubercle bacillus in sputum (Fränkel and Pfeiffer).

be grown on glycerin-agar or on the potato. The grass or butter bacillus has staining properties much like those of the tubercle bacillus, and since this organism is commonly found on hay and straw it should be carefully excluded in the study of milk, butter, etc. Both the lepra bacillus and the smegma bacillus resemble the tubercle bacillus in their manner of taking stains, but neither organism is capable of cultivation.

Inoculations into the guinea-pig and other animals are succeeded in three to six weeks by the appearance of elementary tubercles—first, locally, and then in other organs of the body.

Chemical Products.—The growth of the bacilli is possibly attended by the formation of secretory products. Thus an albuminoid substance has been separated, and this when injected into the body of an animal produces slight fever. The albuminoid separated from cultures of tubercle bacilli is a nuclear proteid, and not a specific toxin. The constitutional features of the disease may be ascribed, in part, to the circulation of these poisons in the blood, but principally to the pus-producing organism.

Bovine Tuberculosis.—The disease is common among cattle (10 to 20 per cent.), and Koch first pointed out certain differences between the bovine bacillus and the bacilli of human and animal tuberculosis. Smith's¹ studies show that the bovine bacillus possesses the greater virulence. It is known that the human bacillus infects cattle with difficulty, while "the bovine bacillus infects animals, and probably also man, with great readiness" (MacFarland).² Koch,³ in an address before the English Congress on Tuberculosis, said that man is rarely infected

¹ *Trans. of the Assoc. of Amer. Phys.*, 1896, xi., p. 78, and 1898, xiii., p. 417.

³ *Jour. Compar. Path. and Therap.*, Sept., 1901.

with bovine tuberculosis. At the seventh International Congress on Tuberculosis (1908), Koch stated that he knew of no authenticated case of pulmonary tuberculosis in which bovine bacilli had been found repeatedly in the sputum. The results of the investigations made by the German Imperial Board of Health show that the dangers from the use of milk and other dairy products derived from cows with tuberculous udders is extremely slight.¹ The British Royal Commission found that one-third of the cases of tuberculosis in children under five years of age were due to the bovine bacillus, hence attention must be paid to this factor in connection with methods of prophylaxis (Woodhead). M. P. Ravenel concludes: (1) That the tubercle bacillus from bovine sources has in culture fairly constant and persistent characteristics of growth and morphology, by which it may tentatively be distinguished from that ordinarily found in man; (2) that cultures from the two sources differ markedly in pathogenic power, affording further means of differentiation, the bovine bacillus being very much more active than the human for all species of experimental animals tested, with the possible exception of swine, which are highly susceptible to both; (3) the tuberculous material from cattle and from man corresponds closely in comparative pathogenic power to pure cultures of the tubercle bacillus from the two sources for all animals tested; (4) that it is a fair assumption from the evidence at hand and in the absence of evidence to the contrary, that the bovine tubercle bacillus has a high degree of pathogenic power for man also.

Sources of the Bacilli.—The chief sources are the sputum of tuberculous patients and the dejecta of persons with tuberculous enteritis and infected meats and milk. The desiccated, germ-laden sputum is wafted into the atmosphere in the form of dust-like particles.

Distribution of the Bacilli.—The tubercle bacilli are found in a viable condition, both (a) inside and (b) outside of the body.

(a) *Inside of the Body.*—As before stated, the number of bacilli found in tuberculous growths varies within wide extremes. In general terms, it may be said that the more rapidly the process advances the greater the number of bacilli present. It must not be forgotten, however, that the activity of the tuberculous processes is intimately connected with the degree of resistance offered by the tissues. A chronic tuberculous focus may establish a fistulous connection with a vein or a lymph-vessel, and thus scatter the bacilli to the remotest parts of the body; and in such instances (as the direct effect of the original number of bacilli present) a chronic is quickly converted into an acute form of tuberculosis. Strauss² demonstrated virulent bacilli within the nasal cavities of healthy persons whose positions necessitated their association with, and frequent presence in rooms occupied by, tuberculous patients.

(b) *The Bacilli Outside of the Body.*—Tubercle bacilli can maintain their existence almost indefinitely outside the body. On the other hand, they probably do not develop or multiply under the usual external influences, but their vitality is extraordinary. Their destruction cannot be effected by freezing nor by desiccation, and they survive for months in water. Their power to resist chemical agents (nitric acid, etc.) is also very great, but they may be destroyed by boiling for four or five minutes or by exposure to the direct solar rays from four to eight hours

¹ A. Weber in Heft 10 of *Research Work in Tuberculosis*.

² *Münch. med. Wochen.*

(Jousset). In milk they may be destroyed by heating in a closed pasteurizer for a period of twenty minutes at 140° F. (60° C.). Tubercle bacilli are undoubtedly present in all inhabited places, and they may be conveyed for long distances by means of water, food, and fomites. Willson and Rosenberger have shown that the presence of living tubercle bacilli in the urine and the feces is of importance in relation to the infectiveness of sewage and of drinking water.

The *sputum* dries and flies into the atmosphere in the form of dust, which not only floats in this medium, but also settles upon articles of furniture, the floor, the walls of living-rooms, hospital wards, draperies, clothing, bed-linen, etc.; and from these resting-places it may be conveyed back into the atmosphere. It has been shown, experimentally, that the dust obtained from the walls or from the air of rooms and hospital wards occupied by tuberculous patients is frequently, though not invariably, infected. It is the *in-door atmosphere*, laden with bacilli, that is especially liable to be dangerous. In places only rarely frequented by consumptives the dust is usually free from virulent bacilli.

Modes of Infection.—(1) **Inhalation of the Bacilli.**—Inhalation tuberculosis is, doubtless, less common than formerly supposed. There is some question as to the power of dust containing tubercle bacilli to infect persons and animals when inhaled. It has been demonstrated conclusively that when such dust-like material is mixed with the food, infection follows. In view of this evidence it is probable that the particles of sputum floating in the atmosphere are deposited in the mucosa of the nasopharyngeal ring and tonsils, gaining the lymphatics through these structures and passing to the cervical glands, thence to the apices of the lungs. Klebs and Flügge claim that infection may result from moist particles (salivary droplets) thrown off in coughing, and Boston¹ has demonstrated that in 75 per cent. of consumptives, with cavity formation, a fine spray containing tubercle bacilli is emitted during the acts of coughing, sneezing, laughing, and talking. Ravenel² has shown experimentally that tubercle bacilli may be disseminated by cows in coughing. It is highly probable that such spray magnifies the danger of infection from tuberculous cooks and bakers. Occasionally the bacilli attack first the upper respiratory passages (larynx, nose). Usually, however, primary infection takes place in the *smaller bronchi* in the apical area or, less frequently, in a *bronchus*; this is shown by the fact that healed lesions in persons dying of other causes are commonly met with in these situations in the dead-house. The *bronchial glands* may be found to present tuberculous lesions.

It has long been supposed that tuberculosis is a contagious affection; unlike small-pox, scarlatina, and other acute contagious diseases, however, tuberculosis is not transmitted by a single contact with a person ill of the disease. Flick and others have shown that persons who live in close proximity to affected persons frequently fall victims to the disease as the result of prolonged contact.

Flick's topographic study of phthisis in the Fifth Ward of the city of Philadelphia, extending over a period of twenty-five years, shows conclusively that consumption obeys the laws of infectious and contagious diseases. His researches furnish incontestable proof that tuberculosis is limited to

¹ *Jour. Amer. Med. Assoc.*, Sept. 14, 1901.

² *Jour. Compar. Med.*, Jan., 1901.

centers, and each case owes its existence to previous cases in the same house or locality; that a house which has had a case of consumption will probably have others within a few years, and may have a large number of cases in rapid succession; and that approximate houses are considerably exposed.

The *contagious theory* of tuberculosis gains support from the fact that husbands have been frequently observed to contract the disease from their wives, and the latter, since they are more constantly confined in the house, to become infected yet more frequently from the former. Weber has observed the case of a tuberculous husband who lost four wives in succession, another who lost three, and four others who lost two each. In like manner, the statistical studies of Cornet, Niven, Baer, and others show that the disease spreads through factories, prisons, cloisters, and even among the physicians, nurses, and attendants in hospitals for the reception of tuberculous patients, producing a mortality-rate from this disease ranging from 45 to 75 per cent. Seventy-three per cent. of nurses up to the age of fifty die of tuberculosis (Whittaker). Those who are engaged in making the beds, dusting and sweeping the rooms of patients are most exposed; and, on the other hand, better hygienic living among these classes of individuals, and improved hygienic arrangements in prisons, institutions, and hospitals, have been found to reduce the death-rate decidedly. This result is to be accounted for as follows: (a) There is thus established a greater tissue-resistance to the bacillus tuberculosis on the part of the persons exposed; and (b) the germs are thus more widely disseminated. Obviously, then, in institutions in which the proper sanitary precautions are used there may be few if any instances; and from the records of the latter, facts opposed to the contagious theory of the disease can readily be furnished.

(2) *Infection by Swallowing*.—(a) That the milk of tuberculous animals contains the bacillus, and that the use of contaminated milk may infect the human subject, are well-established facts.¹ Gerlach and Klebs long since observed the occurrence of the disease in animals fed with milk from cows affected with the so-called "pearl disease." It is not even necessary that the animal infected should have tuberculous mammitis (Ernst), though some are of contrary opinion (Flick, Sidney Martin, and others). The exact frequency of this mode of infection is not known. Infected animals, especially cows and pigs, that suckle their young very frequently transmit the disease to the latter, the infection usually resulting in intestinal and mesenteric tuberculosis. The bacillus is, in this instance, swallowed and finds lodgment in the *primæ viæ*. Bang has even shown that butter made from the milk of tuberculous cows may be infectious (*vide* also Bovine Tuberculosis, p. 235). Human tuberculosis is entirely analogous, and hence the tuberculous mother is likely to transmit the disease to her suckling offspring. This explains, adequately, why abdominal tuberculosis is frequent in children.

(b) *The meat of a tuberculous animal* (e. g., cow, pig, or fowl) may rarely be infectious, but the bulk of experimental evidence would seem to show that, unless the parts consumed are the seat of tuberculous deposit, infection does not follow. D. H. Bergey,² holds that the lower

¹ See the elaborate statistical studies of Dr. George Cornet: "Die Tuberkulose in den Strafanstalten," *Zeitschrift für Hygiene*, Bd. x, 1891.

² Saunders' *Year-Book* for 1899.

mortality from this disease shown by the Jewish race is ascribable to their careful *meat inspection*. Again, the possibility of contamination during the course of preparation for the market, and during transportation, must be recollected. The experiments of Aufrecht, Chauveau, Klebs, Parrot, Trappeiner, and others show that tuberculosis may be communicated by incorporating with the food the expectoration from tuberculous patients. The introduction into the stomachs of cattle and goats of a single quantity of virulent bacilli is followed regularly in from thirty to forty-five days by the development of tubercles at the tops of the lungs (Calmette and Guérin¹).

(3) **Infection by Inoculation.**—Tuberculosis may be transferred by direct inoculation, as shown originally by Villemin's beautiful experiments upon the eyes of guinea-pigs. Infection may take place, though this is rare, through slight cutaneous lesions (cuts, fissures, excoriations), as the result of accidental inoculation of tuberculous matter. In this manner there is produced a local tuberculosis of the skin, as a rule. Rarely, the contagion is conveyed by the lymphatics to the glands in the vicinity. Persons who follow certain occupations are more or less liable to this mode of infection—*e. g.*, butchers, handlers of hides, dissectors of dead bodies, and, rarely, surgeons. Rare instances occur in divers ways (the bite of a consumptive, a cut from a broken spit-glass, or even from his pocket-knife, as I have seen in one instance).

The handkerchiefs, body- and bed-linen of the patient may infect by inoculation those who handle or wash them frequently, if they chance to have a fissure or excoriation upon the hand. No doubt *lupus* also arises in the same way. Czerny has reported 2 cases of infection by transplantation of skin; Collings and Murray, 3 cases by tattooing (?). The contact of the lips of tuberculous operators with surgical wounds (as in sucking the latter) may transmit tuberculosis, as in the performance of the rite of circumcision. Ravenel² reports 3 cases of accidental inoculation of the skin in man with the bovine tubercle bacillus.

(4) **Direct Hereditary Transmission.**—In exceptional cases the bacillus is found in the fetus *in utero*. In such instances the disease may remain latent, to break forth during childhood or later in life; and though the fetus itself may display no evidence of tuberculosis, the fetal viscera may yet be infective to guinea-pigs (Birch-Hirschfeld). Lehmann³ has reported an undoubted instance of intra-uterine infection. The tuberculous mother died of tuberculous meningitis three days after the birth of her child, and the child lived twenty-four hours. In its spleen, lungs, and liver were found nodules resembling tubercles and containing tubercle bacilli in large numbers. Galtier has inoculated a pregnant animal with the disease, and found that the offspring was, in consequence, tuberculous at birth. The views of Baumgarten upon this question should be accorded careful consideration. This author believes that the contagion may be transmitted and become pathogenic at a variable period after birth—first, because the affection is very frequent in young children, even during the first months or weeks of life; and, secondly, because certain structures, not apt to be

¹ *Ann. de l'Inst. Pasteur*, 1905, vol. xix.; 1906, vol. xx., 609.

² *Proc. Philada. Path. Soc.*, October, 1900.

³ *Berlin klin. Woch.*, July 9, 1895.

accidentally infected, are commonly the seat of tuberculous lesions in children—the bones and joints. After birth the bacillus may at any time either lose its vitality or take on a luxuriant growth. It is not known, however, in what percentage of these cases the lungs, intestines, peritoneum, and lymph-glands are free from tuberculous lesions. Küss disputes the theory of the latency of the tubercle bacilli, and contends that latent foci do not exist before the age of three months; that they are rare before the first year, when they mature progressively.

Two facts deserve to be here emphasized: First, that a child born of tuberculous parents is more receptive than one born of healthy stock; and second, that it is more liable to accidental infection.

The instances of direct transmission that have been traced occurred through *tuberculous mothers*. The observations of Csokor¹ upon hereditary tuberculosis in cattle also corroborate this dictum. Friedman,² on the other hand, has practically demonstrated the possibility of transmission of tubercle bacilli through the semen. Vignal³ has shown experimentally that invasion by heredity is very rare.

(5) Dock and Chadbourne state that mixed modes of infection occur.

(6) Baldwin invites forcible attention to the danger of infection from the unclean hands of tuberculous patients.

Predisposing Causes.—(1) **Race and Nationality.**—The effect of nationality upon the receptivity to tuberculosis can be studied advantageously in America on account of the cosmopolitan character of the population. The tuberculous tendency on the part of Indians of this continent, even in the most favorable climates, is universally acknowledged, and the fact that the negro race is highly receptive to tuberculosis is also well known. Osler⁴ gives the following corroborative statistics: "Of the 427 cases of pulmonary tuberculosis at the Johns Hopkins Hospital for the two years ending June 1, 1891, there were 41 cases in the colored—*i. e.* about 1 : 10. The ratio of colored to white of all patients in the wards has been 1 : 7." It is more than twice as common in the African as in the white, and still more prevalent with the Indian (W. L. Rodman). At present the number of tuberculous Indians is 120, 24 per 1000 population. Sears⁵ found that in 200 cases of tuberculosis nearly 50 per cent. belonged to the first and second generations of Irish immigrants.

(2) **Hereditary Predisposition.**—The percentage of cases in which heredity can be traced has been variously estimated at from 10 to 40. As before intimated (*vide Direct Hereditary Transmission*), a child reared by tuberculous parents runs great danger of being infected accidentally; and again, a person living in an infected house (with or without the presence of a tuberculous patient) is very liable to become infected, whether his antecedents give a tuberculous history or not. It follows that a correct estimate of the number of cases of phthisis in which hereditary influence plays an etiologic part cannot be obtained. Too much importance has heretofore been attached to the influence of

¹ *Deutsche medizinische Zeitung*, Berlin, Jan. 29, 1892.

⁴ *Text-Book of Medicine*, p. 204.

⁵ *Boston Medical and Surgical Journal*, April 4, 1895.

inherited constitutional peculiarities to the exclusion of other potent factors, especially an infective environment. Moreover, a similar degree of predisposition may be acquired as the result of certain debilitating influences (childbirth, defective food-supply, close living- or working-rooms). An inherited tendency to tuberculosis is more unfailingly transmitted through the mother than the father. Multiple appearance is commoner in families with tuberculous parents (Dock and Chadbourne). Children begotten of parents who are drunkards, or who suffer from certain chronic incurable diseases (syphilis, cancer, etc.) at the time of the birth of their children, are liable to inherit a condition of the system that greatly increases morbidity, unless the tendency is overcome by a proper environment, together with systematic physical training during the first years of life. Moreover, persons who have the so-called tuberculous diathesis are frequent sufferers from catarrhal affections, especially of the respiratory organs. The latter condition forms a marked predisposing factor; yet, on the other hand, tuberculosis is met with in persons of robust figure.

The older authors of medical text-books describe two types of conformation—the *tuberculous* and the *scrofulous*. The latter has a heavy figure, thick lips and hands, large, thick bones, and an opaque skin; the former, a light figure, bright eyes, thin skin, oval face, and long, thin bones. The phthisical type of the chest will be referred to in connection with the physical signs of pulmonary tuberculosis. Here emphasis should be given to Cohnheim's view, which is for the greater part correct, to the effect "that the so-called phthisical habit is not an indication of a tendency to, but actually of the existence of, tuberculosis." Whilst the recognition of a pre-tubercular condition has its practical bearing, it must be recollected also that the term implies merely a "delicacy of constitution, incomplete growth, and imperfect development" (Fagge).

(3) **Previous Infectious Diseases.**—That there is no tendency to the transition of other diseases into tuberculosis, as was formerly supposed, cannot now be questioned in view of the undoubted specific nature of the latter disease. Tuberculosis is, however, embraced among the sequelæ of many acute infectious and chronic diseases—influenza, measles, pneumonia, whooping-cough, typhoid fever, cirrhosis of the lungs, and diabetes mellitus (the latter disease involving a predisposition to the former)—for the reason that they render the tissue-soil, especially that of the respiratory tract, more favorable to tubercular infection. Dock and Chadbourne have analyzed 100 cases of adult tuberculosis (bacillary phthisis); it developed rapidly after influenza in 16, and followed pneumonia in 9. It seems proper to mention here the fact that certain other diseases are thought by most writers to display an antagonistic effect (chronic valvular disease, pulmonary emphysema, etc.).

(4) **Age.**—This affects predisposition decidedly, though tuberculosis may occur at any or all times of life. Certain forms of tuberculosis are especially frequent in young children (meningeal, mesenteric, and lymphatic).

Pulmonary tuberculosis is most common between *twenty* and *thirty*. It is more rare during early childhood and in the aged, and the cases that occur in young children are likely to be rapid in their progress.

(5) **Sex.**—Predisposition has but slight relation to sex. Females are,

however, somewhat more liable than males, and pregnancy in particular is a disposing factor. Again, when tuberculous females become pregnant the progress of the affection is accelerated, and even more so by the period of lactation. Regarding tuberculosis as being pre-eminently a house-disease, females are more exposed to contagion than males, because they are more closely confined in-doors.

(6) **Climate and Soil.**—Humidity of the soil and abundant atmospheric moisture increase the prevalence of tuberculosis. It is especially common in regions in which sudden variations of temperature, or protracted cold with dampness, prevail. This increase is most probably associated with a heightened vulnerability, due to an increased tendency to catarrhal affections of all kinds (Osler). It has been shown that proper drainage of marshy districts has diminished, to some extent, the frequency of this disease (Buchanan), and, on the other hand, mountainous districts are often remarkable for freedom from the disease.

Local Causes.—(1) **Occupation.**—Persons whose employment exposes them to different forms of irritating inhalations are particularly liable. In such, however, there is usually first developed a fibroid induration (*vide* Pneumonokoniosis), and the latter in turn is followed by pulmonary tuberculosis. The continual inhalation of an atmosphere laden with noxious particles, such as is met with in ill-ventilated and overcrowded working or living apartments, renders the tissues more vulnerable.

(2) **Bronchial Catarrh.**—An acute catarrh of the small bronchi prepares the soil for tuberculous infection. Frequently, however, this is the first step in tuberculosis, since the latter disease almost invariably begins as a local catarrhal process, involving the smaller apical bronchi. Here may be pointed out that gastro-intestinal catarrh (of protracted duration—H. M. King) increases the receptivity for tuberculosis.

(3) **Tubercular Pneumonia.**—In like manner, pulmonary tuberculosis may follow an unresolved pneumonia, but such cases are, as a rule, instances of tuberculous pneumonia primarily.

(4) **Hemoptysis.**—According to some authors, hemoptysis is potent in producing pulmonary tuberculosis. It is, however, certain that in most instances in which it appears to precede phthisis, and to exert a causative influence, it is in reality a symptom of existing tuberculosis.

(5) **Pleurisy** may be, though rarely, the starting-point of phthisis. Its predisposing effect may be attributable to compression of the lung, thus interfering with the respiratory excursions, or to the bronchitis which is frequently associated. Pleurisy sometimes initiates fibroid induration, which may then terminate in a tuberculous affection; but the fact is to be emphasized that a very large proportion of the cases of apparently primary pleurisy are tuberculous in nature.

(6) **Intrathoracic Tumor.**—Tuberculosis is often associated with intrathoracic tumors, and especially with aneurysm. Fehde¹ has reported 3 interesting cases of the kind.

(7) **Congenital or acquired contraction of the orifice of the pulmonary artery** predisposes markedly to tuberculosis. The lungs are often found to be undersized and ill-nourished from birth.

(8) **Trauma.**—Injuries to the chest-wall, with or without laceration of the lung, are frequently followed by pulmonary tuberculosis. The explanation of this association is to be found in the fact that trauma

¹ "Lungentuberculose mit Brusthöhlengeschwülste," *Inaug. Diss.*, Leipzig, 1894.

increases largely the susceptibility of the parts injured by diminishing phagocytic activity—the natural power of resistance. It is a familiar observation in surgical practice that after injuries to, or operations on, joints, tuberculosis, often acute, frequently ensues—in about 8 per cent. of the cases.

TUBERCULOSIS OF THE LYMPH-GLANDS.

(*Scrofula.*)

Scrofula implies tuberculous infection, and scrofulous material inoculated upon susceptible lower animals, especially guinea-pigs and rabbits, invariably causes tuberculosis. The virus is, however, less virulent than that derived from other sources, and this explains the slow progress and often latent character of tuberculosis of the glandular system. A major predisposing factor is *age*, this form of tuberculosis preponderating in children. Hecker, from an examination of the records of the Munich Pathological Institute, found that in 147 cases of tuberculosis among children the lymphatics were affected in 92 per cent.; and in young adults tuberculous adenitis is not uncommon. It is rarely met with also during and after the middle period of life. The lesions generally remain limited to the glands first infected—*i. e.*, the cervical, mesenteric, etc., as the case may be—and this for the reason that the natural powers of resistance in the tissues are often able to oppose the march of the destructive forces. Another predisposing condition is an *acute* or *chronic catarrh* of the mucous membranes.

The cases are all divisible into two groups: (1) Local tuberculous adenitis, and (2) general tuberculous adenitis.

(1) **Local Tuberculous Adenitis.**—(*a*) **Cervical.**—This is the most frequent form, and is especially common among children.

Etiology.—Of 2035 persons examined by Valland, enlarged cervical glands were found between the ages of seven and nine in 96 per cent.; between ten and twelve in 96.1 per cent.; between thirteen and fifteen in 84 per cent.; between sixteen and eighteen in 69.7 per cent.; and between nineteen and twenty-four in 68.3 per cent. Tubercle bacilli were found in the cervical lymph-glands in about 68 per cent. of adults. Negroes are found to be more prone to the affection than whites.

Mode of Infection.—I have stated before that tubercle bacilli are sometimes found on the nasal mucous membrane of healthy persons. The presence of an acute or chronic catarrh of the nasopharynx may now lower the resistance of the tissue-cells, so that the bacilli may gain access to the lymph-current, and through the latter to the neighboring glands, setting up tubercular adenitis. The cervical lymph-glands, however, do not furnish a highly favorable soil for the growth and development of the bacilli, and hence the tendency toward latency.

The *tonsils*, owing to their free communication with the atmosphere, in which there is a wide diffusion of tubercle bacilli, may be primarily infected. Friedman suggests that primary tuberculosis of the tonsils is usually set up by infection through the food. But here also, as in the case of other glandular structures, there is a tendency for the affection to become encapsulated, for the reason that the tissue-soil after a prolonged contest generally gains the ascendancy over the invading bacilli. The latter may, however, under certain favorable conditions, break down the

barriers opposed by nature and effect a lodgement in the cervical glands, or even become widely diffused through the economy. Thus Kinckmann in 64 autopsies found 25 cases of tuberculosis, in 12 of which the tonsils were affected.

A third mode of infection of the cervical lymph-glands is through the medium of slight injuries and abrasions of the skin or certain forms of skin-eruptions (eczema, etc.). These serve as doors of entrance for the bacilli, which find their way into the neighboring lymph-glands through the lymph-channels. Compared with infection from within, this mode is most probably much less frequent.

Symptoms.—The main feature is a *visible enlargement* of the affected cervical glands, chiefly the submaxillary. At first the glands are too small to be even palpated; later, they can be felt as small, firm tumors underneath the skin. By and by they appear as visible protuberances, ranging in size from that of an English walnut to that of a hen's egg or even larger. The *skin* over the enlarged gland is freely movable, as a rule; less frequently it becomes adherent—an indication of suppuration. When an abscess forms and is allowed to open spontaneously, there remains a chronic discharging sinus. Suppuration is attended with *fever*, *anemia*, and *emaciation*. In well-marked cases the separate tumors coalesce, forming large and irregular masses. The affection is usually bilateral, though almost invariably it is more marked on one side than on the other.

Not infrequently, in addition to the enlargement of the submaxillary, post-cervical, and supraclavicular glands, there is also involvement of the axillary, as was the case in a fatal instance in my own practice. The patient was a male child, eight years of age, who developed pulmonary tuberculosis. It may reasonably be assumed that the bronchial glands also become implicated, and may excite lung tuberculosis.

The *diagnosis* is based upon the history and the associated evidences (keratitis, conjunctivitis, eczema of the face, nasopharyngeal or bronchial catarrh), coupled with the glandular enlargement. Bacilli have occasionally been found in the purulent discharge from abscesses. Otis applies the tuberculin-test, and obtains positive reactions in 62 to 69 per cent.

The *course* of this affection is exceedingly slow, often extending over a number of years. Many cases, however, recover after timely surgical intervention. On the other hand, neglected cases are a menace to the life of a patient, since they may be followed by diffusion of the bacilli, with the development of a fatal form of disease.

(b) **Bronchial.**—Tuberculosis of the bronchial glands may be primary, or secondary to infection of the lungs, and it is commonly preceded by or associated with *bronchial catarrh*, which is its chief predisposing cause. The primary form is met with frequently in young children, the mediastinal lymph-glands being affected uniformly in 127 cases at the New York Foundling Hospital (Northrup).

The bronchial and tracheal glands are the receptacles for all foreign substances, including the tubercle bacilli that are not dealt with by the broncho-pulmonary phagocytes. After infection with tubercle bacilli the lymph-glands become swollen, tumefied, and are the seat of caseous change; later they may undergo calcification or proceed to abscess-for-

mation. The latter may rupture either into the lungs, into the trachea or the bronchi, or into a pulmonary blood-vessel.

Symptoms.—If a fistulous communication be established with the air-passages, *cough* and *expectoration* of purulent material, blood, and caseous matter containing bacilli will be noted.

Secondary infection of the lung may occur in this manner. When rupture takes place into a vessel systemic infection promptly follows. Tubercular adenitis involving mediastinal lymph-glands may also lead to infection of the pericardium and then proceed to tuberculous pericarditis.

(c) *Mesenteric (Tubercles Mesenterica).*—This may be *primary* or *secondary*, the latter being common as a secondary infection to intestinal tuberculosis.

The former is rare, however, and the intestinal catarrh with which it is associated is doubtless tuberculous in the vast majority of cases. The mode of infection has already been pointed out. The lesions presented are similar to those met with in tuberculous bronchial glands.

The *symptoms* are not always distinctive, and may be entirely negative during the life of the patient; hence the condition is often incidentally discovered during the post-mortem examination. The *local symptoms* when marked are due in the main to an associated peritonitis. The abdomen is painful and more or less swollen. *Peritoneal effusion* is present, and sometimes sufficient in amount to be detected by the customary physical signs. Large and small *nodules* may sometimes be felt. *Diarrhea* is a marked and an obstinate feature and is usually due to tuberculous intestinal ulcers. *Fever* of an intermittent type is almost constantly present, causing emaciation, and the objective changes (pallor of skin, mucous membranes) due to anemia become pronounced. This form of tuberculosis may persist as a local condition, but there is danger of extension to other organs (pleura, lungs). On the other hand, in the adult pulmonary tuberculosis may be followed by involvement of the mesenteric glands without involvement of the intestines, and in such instances there occurs an extension by contiguity along the course of the lymphatics that pass through the diaphragm, and finally, in adults, primary tuberculous new growths may be met with in the mesenteric glands.

Diagnosis.—A probable diagnosis can usually be made if careful attention be paid conjointly to the symptoms, physical signs, and course of the affection. The detection in a child of a tumor which may be moderately hard, doughy, or even fluctuating will aid materially in the diagnosis, and will also afford evidence of tuberculous disease in other organs.

(2) *General Tuberculous Adenitis.*—This term implies tuberculous disease of the lymph-glands throughout the body, with little if any involvement of other organs; it is a rare condition. The affection may begin as a local tuberculous lymphadenitis, nearly all the rest of the glands of the body becoming secondarily implicated. The primary seat of the trouble is perhaps most frequently the cervical lymph-glands, though in one instance observed by myself the mesenteric glands first became affected, the case terminating in pleuro-pulmonary tuberculosis.

Symptoms and Diagnosis.—There is *protracted fever*, the temperature being of the remittent or intermittent type. *Wasting and debility*

are progressive until the patient presents a decidedly puny aspect, while the lymph-glands that are accessible to inspection and palpation are more or less enlarged and manifest a marked tendency to *suppuration*. The affection is usually *chronic*, though very exceptionally it may exhibit an acute course. One of the chief dangers overhanging the sufferer in this affection is that, owing to liberation of the bacilli, the meninges or the lungs may become tuberculous; these cases may also eventuate in death from *asthenia*. Cases in which the glands are but little enlarged, while the *general features* are marked, are puzzling. On the other hand, when the superficial lymph-glands are greatly enlarged, the affection may bear a striking resemblance to Hodgkin's disease. Indeed, certain recent writers hold that generalized tuberculous adenitis and pseudo-leukemia are etiologically identical (*vide* Hodgkin's Disease, p. 484).

ACUTE TUBERCULOSIS.

This form of tuberculosis is characterized anatomically by the rapid development of miliary tubercles in many and widely-separated parts of the body. In some instances the new growths are pretty evenly distributed through all the organs of the body, manifesting the clinical symptoms of an *acute general infection*. In other instances there is a tendency to centralization of tuberculous growths, as, for example, in the lungs (pulmonary variety) or in the meninges of the brain and spinal cord (meningeal variety).

Pathology.—The fact is to be emphasized that somewhere in the body there is an old tuberculous focus. Apart from this primary lesion, the anatomic changes consist in the widely disseminated miliary tubercles. Their most frequent seats are the lungs, liver, and spleen; less commonly, the marrow of the bones, the heart, the choroid, and the meninges. In some of the organs, particularly the meninges, lungs, etc., the tubercles may be readily perceived by the naked eye, while in others they frequently cannot be detected without the aid of the microscope. It must not be forgotten that in some of the more protracted cases the nodular tubercles may grow into foci of considerable size, ranging from that of a lentil to that of a pea.

Etiology.—This has been, in the main, given in connection with the general etiology of tuberculosis (*vide supra*), though a few special points remain to be adduced. The acute forms of tuberculosis are decidedly more frequent during infancy and childhood than during adult life, and with few exceptions the cases are secondary to a local tuberculous focus in one or more lymph-glands (tracheal, bronchial, mesenteric) or in the lungs. More rarely a pre-existing tuberculous focus in the kidneys, the bones, or the skin may give rise to the affection, as may the occurrence of certain other acute infectious diseases (such as measles, whooping-cough, and influenza) in children, and typhoid fever and lobar pneumonia (especially with delayed resolution) in adults.

Modes of Infection.—Most frequently there is established a fistulous connection between the local tuberculous focus and a vein, especially the pulmonary vein. Under these circumstances there may be large numbers of bacilli discharged into the blood-stream; but oftener only small

numbers of bacilli enter and subsequently multiply, inducing general infection (Ribbert and Wild¹). A second mode of infection, though decidedly more rare than the above, is the rupture of a tuberculous focus into the thoracic duct, in which case the tuberculous material passes almost directly into the subclavian vein.

Clinical History.—That miliary tubercles may exist in many organs of the body (liver, heart, etc.) without giving rise to symptoms is a noteworthy fact. Cohnheim and Manz have discovered miliary tuberculosis of the choroid with the aid of the ophthalmoscope alone.

The following forms of the disease may be distinguished:

GENERAL MILIARY TUBERCULOSIS.

(a) TYPHOID FORM.

The **symptoms** are those of a general infection of the body, there being in most cases a period of *incubation*, during which the patient complains of malaise, headache, chilliness, feverishness, and increasing debility. Rarely, the *onset* is comparatively *sudden*. The reaction of the nervous system against the poison, which is now scattered to all parts of the body, is shown by such symptoms as the *fever*, which rapidly increases, a *rapid, feeble pulse*, and *mental dulness* or *delirium*. The *tongue* becomes dry, and sometimes also brown. The *respirations* are accelerated, and there is more or less *cyanosis*, with which symptom is associated a peculiar and *characteristic pallor* of countenance. Coincidentally with the febrile exacerbations the *cheeks* wear a circumscribed blush. Among the rarer early symptoms is epistaxis. The patient soon becomes either profoundly prostrated or anxious: if, as sometimes happens, the course is protracted, *weakness*, *anemia*, and especially *emaciation* are well marked and assume diagnostic importance. These cases sometimes pass into the pulmonary or the meningeal form, the patients often succumbing speedily to such localized developments.

Fever.—The temperature usually pursues a high range, although there are a few cases in which the entire course is afebrile. Again, it occurs not infrequently that the temperature is normal or nearly so for a short period. The usual temperature-curve ranges at first between 102° and 104° F. (38.8°–40° C.), and then continues to rise, with the development of the serious general condition in a way exactly similar to that observed in typhoid fever. In many instances the fever is irregularly remitting, at least at intervals, if not so constantly. Thus, periods of irregular fever may alternate with others of continued, and later deeply remittent or distinctly intermittent, fever.

Nervous Symptoms.—In most cases the nervous symptoms are not prominent. In a smaller number headache, vertigo, delirium, and often stupor, become marked at an early stage and may persist. They are due to the general infection.

Circulatory System.—The pulse is small, and its rate is out of proportion to the fever, varying from 100 to 140 or higher. It may become irregular, particularly if the meninges be involved.

Respiratory System.—The breath is somewhat hurried and labored; there is a cough, but it is not annoying as a rule; and there is a slight expectoration, which is not characteristic. If there be present simul-

¹ *Deutsche medicinische Wochenschrift*, Dec. 30, 1897.

taneously in the lungs an old tuberculous focus, the expectoration may be more profuse and typical. The bacilli are also absent from the sputum unless an old tuberculous lesion exists in the lungs.

The physical signs are those of a diffuse bronchitis, though signs of consolidation or pleurisy may develop late in the course of the affection. Such signs, however, may be evidences of an old tuberculous affection.

Digestive System.—As before noted, there are anorexia and a dry tongue (symptoms due to the systemic infection), while vomiting may occur at the outset, and excessive thirst is common. The spleen usually becomes enlarged, though only to a slight extent, as a rule.

Ocular Symptoms.—The important symptom presented by the eye is the presence of choroid tubercles, which may be determined by a careful ophthalmoscopic examination. Their absence, however, does not militate against the diagnosis of this disease. Their demonstration is always exceedingly difficult, and only possible with the skilled ophthalmologist. Tileston has described an eruption, in cases occurring among children, which consists of scattered, discrete papules about the size of a pinhead, and on these are tiny vesicles with cloudy contents or minute pustules, followed by drying, with slight incrustation.

Diagnosis.—In the following table I have endeavored to contrast points of dissimilarity between this disease and typhoid fever :

ACUTE GENERAL MILIARY TUBERCULOSIS.

Family history of tuberculosis, or presence of an old focus.

Evolution of the disease not characteristic.

Epistaxis rare.

Fever-curve of decidedly irregular type.

Pulse rapid, out of proportion to fever.

Respirations rapid and labored.

Face dusky, with peculiar pallor.

Abdominal symptoms are not suggestive.

No characteristic eruption.

Widal reaction absent.

Knee-jerk may be absent.

Choroid tubercles may be detected.

Tubercle bacilli rarely demonstrable in the blood.

Hemorrhage from bowels exceptional.

Perforative peritonitis absent.¹

TYPHOID FEVER.

Coexistent with an epidemic or following previous cases of typhoid.

Evolution of the disease is characteristic.

Epistaxis a common early symptom.

Temperature-curve of the continued type.

Pulse often dicrotic ; slow in proportion to fever.

Respiration moderately increased.

No duskiness of face.

Abdominal symptoms (stools, enlarged spleen, tympanites, etc.) suggestive.

The eruption (appearing in successive crops) is distinctive.

Usually present and pathognomonic.

Knee-jerk never wanting.

Choroid tubercles absent.

Cultures from venous blood show typhoid-bacilli. They may also be found in the stools and urine.

Hemorrhage from the bowels common.

Perforative peritonitis often present.

The tuberculin test may prove an aid to diagnosis in cases pursuing an apyrexial course.

(b) PULMONARY FORM.

Though all gradations between the typhoid and the pulmonary types occur, the latter should be recognized and briefly described. It may develop *suddenly*, the ushering-in symptom being sometimes a *chill*, though more frequently there is a *premonitory period*, during which

¹ See also Differential Diagnosis of Typhoid Fever.

the general health fails materially. Some acute illness, as measles or whooping-cough, in which there has been marked catarrhal bronchitis, often constitutes the point of departure for this variety.

The *respiratory symptoms* are early prominent, and later preponderate in the clinical picture. From the start there is dyspnea, and this gradually increases until the respirations become rapid (40 to 60 per minute). When dyspnea becomes pronounced, the face presents a characteristic cyanotic pallor. The cough at first is moderately severe, but it soon becomes troublesome, being frequent and attended with a slight expectoration, which, however, is non-characteristic.

The *physical signs* are those of broncho-pneumonia, and the latter may or may not be preceded by the signs of generalized bronchitis. With the onset of consolidation there appear spots that yield either dulness or a tympanitic resonance on percussion, and broncho-vesicular breathing with numerous subcrepitant râles on auscultation.

The *general symptoms* are marked from the beginning. The *fever* is high—from 103° to 105° F. (39.4° – 40.5° C.) or often higher. The pulse ranges from 100 to 140, is small, feeble, and sometimes irregular, and it may be more rapid still during the advanced stage of the affection (see Fig. 20). Cerebral symptoms rarely appear.

The *course*, as a rule, is more prolonged than that of general miliary tuberculosis, except in children, in whom it often runs an exceedingly acute course. As the end approaches the signs of suffocation are gradually intensified, and finally lead to a fatal termination.

Diagnosis.—The diagnosis is difficult; but a family history of tuberculosis, a knowledge of the pre-existence of a tuberculous focus or of an antecedent predisposing affection, will aid in its recognition. Tubercle bacilli are perhaps not demonstrable in the sputum unless an old tuberculous lesion is present. In doubtful cases, however, an attempt should be made to detect the bacilli in the blood. Occasionally either tuberculous meningitis or peritonitis supervenes, and aids in removing the doubt, and in a small percentage of the cases choroid tubercles are detectable. These points, together with the more marked general symptoms, will usually enable the clinician to distinguish this variety of tuberculosis from *non-tuberculous broncho-pneumonia*.

(c) CEREBRAL OR MENINGEAL FORM (TUBERCULOUS MENINGITIS).

This variety is of quite frequent occurrence, appearing in not less than 50 per cent. of the cases of miliary tuberculosis. When it develops, the symptoms referable to other organs than the meninges are in abeyance. With reference to the *etiology*, the fact needs to be emphasized that most cases occur between the ages of two and seven years; it may, however, be met with at any time of life. The affection frequently has its origin in tuberculous bronchial glands (Jacobi), and the history of a fall is common. A few cases have been found to be associated with erythema nodosum. Exceptionally, the meninges are primarily involved.

Pathology.—The chief site of the tubercles in children is the pia mater at the base of the cerebrum (basilar meningitis), while in adults the pia at the vertex is more apt to be involved. The membrane sur-

FIG. 20.—Chart of a case of acute pulmonary tuberculosis. Mrs. M—, aged twenty years. Black, temperature; red, pulse; blue, respirations.

rounding the tubercles may not be inflamed, there being a simple tuberculous deposit. On the other hand, more or less inflammation, with sero-fibrinous or fibrino-purulent exudation, is generally present in the region of the base. This exudate is usually abundant in the Sylvian fissures, and may find its way to the external surface of the hemispheres. It is gray in color, transparent, and gelatinous, and contains in its meshes the tubercles, which appear as grayish-white bodies, and which, in cases of equal severity, may be either numerous or scanty. They may be scarcely visible to the naked eye, but may vary from the size of a pinhead to that of a French pea. The branches of the Sylvian artery may be implicated, either owing to the direct pressure of the exudate or to the obliterating arteritis produced by a tuberculous infiltration. The pia looks like wet blotting-paper over the quadrangle at the base (Gray). Elsewhere it is thickened and opaque, though easily detachable. Osler says: "The arteries of the interior and posterior perforated spaces should be carefully withdrawn and searched, as upon them nodular tubercles may be found when not present elsewhere. In doubtful cases the middle cerebral arteries should be very carefully removed, spread on a glass plate with a black background, and examined with a low objective. The tubercles are then seen as nodular enlargements on the smaller arteries." Involvement of the chief vessels that nourish the walls of the ventricles and the ependyma, and stretch from the vermis cerebelli forward over the quadrigemina, explains the constant presence of a turbid fluid in the ventricles, with softening of their walls. As the result of undue intraventricular pressure the cerebral convolutions become more or less flattened, with effacement of the sulci. The cortex, to a variable depth, is generally the seat of red softening, and more rarely of white softening alone. The tuberculous infiltration involves the cranial nerves.

Histology.—The tubercles grow in the perivascular sheaths, which are often distended with lymphoid and epithelioid cells, and there is observed not infrequently a thrombosis of the arteries and of the venules of the pia, obliterating their lumen. The pia mater is gradually thickened through cellular infiltration, and in a small proportion of the cases the spinal meninges are similarly involved, chiefly in the cervical portion of the cord.

Symptoms.—There is a *prodromal period* which lasts one or more weeks, during which the patient (usually a child) is pale, peevish, has headache and photophobia, and grinds its teeth during sleep; the tongue is coated, appetite impaired, and there may be occasional vomiting, either propulsive or regurgitative. Constipation is present and may be marked. Among rare premonitory symptoms are slight hyperesthesia of the abdomen and a diminished urinary secretion. A tendency to *emaciation* is quite constant. These prodromal symptoms present variations as to their number and combinations in different cases. In few instances only is the onset acute. The symptoms usually indicate basic meningitis, and at first there is associated considerable mental excitement; later there are pressure-symptoms (caused by the exudate), with total loss of the mental faculties.

(1) **Stage of Cerebral Excitement.**—The *invasion* is generally gradual, or even quite insidious, its most characteristic phenomena being *severe*

vomiting, marked headache, and chills followed by fever. Certain other symptoms now arrest the attention, such as extreme irritability, screaming, and great obstinacy, and occasionally drowsiness appears early. When the onset is sudden the disease may be disclosed by convulsions, paralysis, wild delirium, or coma. The established disease exhibits certain distinctive features. The pain is often most excruciating, causing the child to utter short penetrating screams (hydrocephalic cry), and in rare instances the sharp cries may be continuous and lead to physical exhaustion. The headache is increased by light, noise, or movement. Vertigo is common; the pupils are contracted at this period; the face pales and then flushes; the pupils alternately dilate and expand; and the expression is sometimes sad, though more often stupid. Generally hyperesthesia or dysesthesia may appear, and there may be a slight mind-wandering at night, though active delirium is rare. *Tâches cérébrales* may be obtained, but are not characteristic. The patient is intolerant of every form of disturbance. All the symptoms of the prodromal stage are now aggravated; slight muscular twitchings and sleep-starts occur; the vomiting is apparently causeless, and may be frequently repeated; and constipation persists.

Fever is present, but is of slow development, and rarely rises higher than 102° or 103° F. (39.4° C.) in the evening. The *skin* is dry and harsh. The pulse is slow or moderately accelerated, but soon quickens to 120 or even 130, and later it may be irregular. At times the *pupils* are unequally contracted, and ptosis is usually an early sign.

(2) **Second or Transitional Stage.**—The symptoms of cerebral irritation now abate, the patient becoming more quiet, while mental dulness often supervenes. The vomiting and headache gradually subside, and the child rarely cries out. The abdomen is now distinctly scaphoid and the head occasionally retracted. Constipation is obstinate. The evidences of localized organic foci, such as slight twitchings of the muscles of the face, followed by strabismus, ptosis, or paralyzes of the face or limbs, may appear. Generalized convulsions may occur, and muscular tremors and athetoid movements may appear. Both pupils (or one only) may be dilated as intracranial pressure develops; patchy flushing of the face is common. The respiration is now irregular and sighing.

(3) **The Stage of Paralysis.**—On account of the exudation the mental faculties are abolished, so that the patient is comatose, though convulsions or localized spasms of the muscles in different parts of the body (neck, back, limbs, etc.) may be observed. Optic neuritis develops, while the paralysis of the ocular muscles above noted deepens. The pupils are dilated, the eyes are partly closed, and the eyeballs at intervals slowly and alternately move in a lateral direction. Hemiplegia sometimes develops, and more rarely monoplegia, affecting the face or one of the extremities. There may be paralysis of the third nerve, with involvement of the face, hypoglossal nerve, and limbs on the opposite side (a combination of symptoms first observed by Weber), consequent upon a lesion localized in the internal inferior portion of the crus. Monoplegia of the right side of the face has been observed in a few instances, associated with aphasia. Exceptionally aphasia and brachial monoplegia have been combined. The temperature in the early part of

this stage usually rises to 103° F. (39.4° C.) or higher, but later it may drop to a subnormal level, and in rare instances as low as 94° F. (34.4° C.). Immediately preceding the fatal termination the temperature may rise to 106° or 107° F. (41.6° C.), the pulse becoming frequent, small, and irregular. Anesthesia comes on with general muscular relaxation.

Occasionally a *typhoid state* (great prostration, dry tongue, diarrhea, etc.) may develop, and Cheyne-Stokes respiration is almost invariably present, preceding the fatal event. Leukocytosis has been observed.

Ophthalmoscopic Examination.—The ophthalmoscopic appearances are—hyperemia of the disk, later the changes belonging to neuritis (swelling and striation) appear, and choroidal tubercles may be detected.

Diagnosis.—This is based: (1) On the reaction to tuberculin; (2) Examination of eyes, which present the characteristic appearance of the choroid coat (Jacobi). Macewen first pointed out that if the patient is caused to assume the upright position with the head inclined to one side, percussion over the pterion gives a tympanitic note which is indicative of internal hydrocephalus. Koplik found this sign present in 34 of 52 cases. *Post-basis meningitis* gives the same symptoms, and lumbar puncture is the only means of diagnosis. In tubercular meningitis the diplococcus intracellularis is not found. *Syphilitic meningitis* and meningitis due to *trauma* may bear a close resemblance to the tubercular form, but the history should prevent confusion.

Clinical Types.—(a) **Mild Type.**—The marked or alarming symptoms (tetanic rigidity of the muscles, convulsions, and paralysis) develop at a late period. In this class should be placed those cases in which the meningitis is but feebly indicated—*e. g.* when it is but a small factor in the condition of acute general tuberculosis.

(b) **Malignant or Rapid Form.**—This type is comparatively rare, occurring most frequently in adult life, while the lesions have their seat almost exclusively upon the convexity. The onset is marked by the most frightful tetanic convulsions, which precipitate a fatal termination in a couple of days.

(c) **Chronic Type.**—Cases pursuing a chronic course are rarely encountered, and the symptoms usually point to localized cerebral lesions (Jacksonian epilepsy, etc.).

Prognosis.—The disease lasts from two to four or five weeks, though chronic cases may continue for several months. When the convexity is implicated, however, the duration is only one or two weeks. It should be emphasized that frequently in the course of well-marked cases a decided remission in the leading symptoms occurs, so that convalescence is suggested; but this is deceptive, and is almost invariably followed by a renewal of the unfavorable features of the affection. A few cases only are recorded in medical literature as ending in recovery.

Freyhan has reported a case with recovery in which the diagnosis was proved by puncture of the spinal canal and the withdrawal of fluid, in the sediments of which tubercle bacilli were found. A. Jacobi has met with 2 cases that terminated favorably, and Leube has also reported a case in which the symptoms were characteristic, and at the autopsy, some years later, old tuberculous lesions were found in the meninges. It is to be recollected, however, that the course of tuberculous meningitis is probably uninfluenced by human agency.

ACUTE PNEUMONIC PHTHISIS.

(Acute Phthisis; Florid Phthisis; Galloping Consumption.)

This may be primary or secondary, the latter form being consequent either upon a localized tuberculous area in the lung, tuberculous pleurisy (acute or chronic), tuberculous peritonitis, or tuberculous disease of some other organ. Acute phthisis may occur at any age, though it is relatively more frequent in childhood and early adult life, but whether primary or secondary, the infection of the lungs is rapid.

Pathology.—Two forms may be recognized: (1) This reveals the appearances of an *acute lobar pneumonia*, one lobe only being implicated, as a rule, though sometimes the whole lung is involved. The process leads to a destruction of lung-tissue, so that a section may show the existence of cavities. The latter are usually small, while surrounding them may be seen tubercles in hepatized tissue, and here and there caseous masses of a yellowish-white color may be visible. These often indicate old or pre-existing foci. It is sometimes exceedingly difficult to distinguish a tuberculous croupous pneumonia from the ordinary form, and the most careful inspection may fail to reveal the presence of elementary tubercles in the acutely consolidated tissue. In cases in which this disease is suspected, however, the opposite lung, the bronchial glands, the peritoneum, and other organs should be carefully examined.

The lesions presented by cases that have run a long course are somewhat characteristic, though not always the same. If the case has had a duration of two or more weeks, apical softening with more or less extensive cavity formation often occurs. Less frequently, a lobe or an entire lung is found to be consolidated throughout, "and converted into a dry, yellowish-white, cheesy substance, in which condition it may remain till the end."

(2) *Presenting the Appearances of Broncho-pneumonia.*—This variety is more common than the previous, especially in children. The evidences of bronchitis affecting the finer tubes, together with consolidation of the lobules to which the tubes lead, are striking. As in ordinary broncho-pneumonia, so here, the solidified areas appear as grayish-red masses in the early stage, while later they are of an opaque-white. The products that fill the air-cells may caseate and break down, with the formation of irregular cavities that vary in size. When large areas are involved they are the result of the fusion of contiguous smaller areas of hepatized tissue. The trouble often begins in the upper lobes and spreads downward, though not infrequently the lower lobes are most extensively involved.

In not a few cases the masses are small, multiple, and widely disseminated throughout the lungs, and miliary tubercles in the lungs or pleuræ are associated with the broncho-pneumonic lesions before described. In nearly all cases signs of pleurisy may be noted, as is shown by pleural adhesions or by deposits of lymph on the pleura. The bronchial glands are also usually infected, and, particularly in children, are the seat of tuberculous processes.

Bäumler has called attention to a type of *tuberculous inhalation pneumonia* consequent upon hemoptysis, the blood and contents of the

cavities being drawn into the finer tubes in respiration. This form of broncho-pneumonic phthisis sometimes follows pulmonary tuberculosis in the early, though more often in its late, stage. On microscopic examination tubercle bacilli are found, though rarely in abundance, in the infiltrated masses and in the walls of the cavities.

Clinical History.—(1) *Acute Cases.*—Preceding the attack, the patient may have “taken cold” or have been in a run-down state; more often, however, he has been apparently healthy. The *onset* is sudden, marked by a *rigor*, *pain in the side*, *fever*, *cough*, and *systemic prostration*, and there may be *bronchial hemorrhage* which may last one or more days. The total amount of blood expectorated may be considerable. In the majority of cases the *expectoration* is mucoid at first, and then becomes rusty-colored, often containing tubercle bacilli, though at first they may be absent and, indeed, not appear until late in the disease. *Dyspnea* appears early, and may soon become extreme, and the fever quickly rises to 104° F. (40° C.) or over. It may be of the continued type, or it may early assume the remittent or hectic type, and with the latter forms of fever, which usually begin about the end of the first week, are associated *night-sweats* and *rapid emaciation*. The prostration of the vital powers is now extreme. The expectoration is more abundant, muco-purulent, and often greenish-yellow in color.

In the course of one or two days after the onset we obtain *physical signs*. Usually, as before stated, there are present the anatomic appearances of acute lobar pneumonia—viz., the complete consolidation of one or more lobes, which is usually followed by signs of softening, provided the patient survives the first week or ten days. The physical signs during the stage of consolidation are precisely the same as in lobar pneumonia. The signs of softening and of cavity will be given in detail below (*vide* Chronic Phthisis).

The *course* is usually rapid, occupying from two to six weeks on the average, though rarely cases that reach the stage of cavity-formation are protracted to three or even four months. Considering the brevity of the attacks, the extreme degree of emaciation (shown especially by the hollow cheeks and temples, pinched nose, and thin hands) is truly remarkable. The patient usually maintains a hopeful state of mind, notwithstanding the rapid downward course of the affection, and it may be admitted that recovery is possible. The parts involved are in such cases destroyed and replaced by fibrous tissue, and it should be remembered that the apex is oftenest involved. It may happen that consolidation only is present in the second lobe affected, while in the upper lobe one or more cavities have already been developed. The pleural crepitating friction is often audible before consolidation is complete.

Diagnosis.—The onset, symptoms, and course during the first week may be those of ordinary lobar pneumonia, but in some cases certain symptoms may arise which will excite suspicion of their tuberculous character in the early stage. Thus, hemoptysis rarely occurs in a pneumococcus infection, and the appearance of the patient, as well as his previous and family history, may also be of a confirmatory character. The points of discrimination have been fully set forth in the section on Lobar Pneumonia (pp. 123, 124).

(2) *Subacute Cases* (rarely acute).—The *onset* is less sudden than in

the former type, while the patient's antecedent condition may either be good or below the *standard*. At the beginning he has *repeated chills*, though *hemoptysis* may be the first symptom which indicates a pre-existing tuberculous focus. The *fever* rises high, and is apt to be irregular from the start; the *pulse* and *respirations* are rapid, and there is a *muco-purulent expectoration* which may either be profuse or scanty. Occasionally it is fetid, and the sputa may early contain *elastic fibers* and *tubercle bacilli*, though more often these are noted after the affection has become fully established. During the progress of the case, also, hemoptysis may arise. Later, drenching *night-sweats* increase the exhaustion and emaciation, which speedily reach an extreme degree, and soon or late a typhoid condition of the system is developed.

The *physical signs* are, at first, those of general bronchitis, with or without indications of pleurisy. Later, small areas of consolidation, which often increase in size, are indicated by impaired percussion resonance or dullness and by broncho-vesicular (rarely tubular) breathing, with subcrepitant râles. These signs may be unilateral, though more often they occur bilaterally. In many cases softening with cavity-formation ensues, with the usual physical signs of this condition.

Course and Duration.—For some time the patient may remain out of bed, although in most instances the disease constantly progresses. Less frequently there are exacerbating periods and remissions. Rarely these cases recover with a loss of more or less lung-tissue. Again, the condition may pass into chronic phthisis. It is important to recollect that the local lesions may become extensive, as the result of fusion of small consolidated masses, until an entire lobe is involved, and when this occurs the symptoms and course simulate those of the acute type. The *duration* ranges from two to eight weeks or more.

Diagnosis.—This variety is frequently confounded with non-tuberculous broncho-pneumonia, and the chief distinctions will be mentioned in connection with the latter disease. *Bronchiectasis* may be accompanied by emaciation, fetid expectoration, night-sweats, and the signs of cavity, and this disease has been mistaken for acute phthisis. Important in the recognition of the latter, however, are marked fever and emaciation. Moreover, the physical signs are more frequently referable to the apices, and the disease is more steadily progressive, running a shorter course than bronchiectasis. The sputum contains tubercle bacilli.

Acute Broncho-pneumonic Phthisis in Children.—The belief that the form of broncho-pneumonia that so frequently follows certain infectious diseases (measles, whooping-cough, etc.) is in the majority of instances tuberculous has been steadily gaining. Osler recognizes three groups of cases: (*a*) Those in which the child suddenly becomes ill while teething or during convalescence from fever, with high temperature, severe cough, and the signs of consolidation of one or both apices. Death may occur within a few days. To the naked eye the lesions do not appear to be tuberculous. (*b*) In this group the children show the ordinary symptoms of broncho-pneumonia, and the cases are more protracted, death occurring about the sixth week. (*c*) The child feels ill during convalescence from an infectious disease, fever, cough, and dyspnea being present. The intensity of the symptoms abates within a fortnight, and the physical examination shows the presence of diffuse bron-

chitis with scattered minute areas of consolidation. Many of these cases develop into chronic phthisis.

CHRONIC TUBERCULOSIS.

(*Chronic Pulmonary Tuberculosis; Chronic Ulcerative Phthisis.*)

This form is much more common than the acute, the term embracing sub-varieties to which attention will be incidentally directed. Its most typical clinical form follows a mixed infection as a result of a septic element superadded at some time to the primary tuberculous infection.

The Causal Factors have been detailed under General Etiology.

Pathology.—The pathologic characters of tuberculosis in general have been already presented, but it will be necessary to describe briefly the special anatomic conditions met with in *chronic ulcerative phthisis*.

The post-mortem appearances of the lungs in chronic pulmonary tuberculosis are remarkable for their great diversity, not only in the extent of tissue involved, but also as to the character of the morbid processes. Often the associated lesions form no unimportant part of the picture. In nearly all fatal cases the most advanced and extensive lesions are found near the apex, and, as a rule, the entire upper lobe of one of the lungs is implicated. In addition, it is observed that the destructive process has extended to the lower lobe of the same side, and later to the apex of the opposite lung. Though both lungs are affected in fatal cases, they represent different stages of the disease. The case is very different in an old and cured tuberculosis of the lungs, such as is frequently met with in persons who have died of some other affection. Here the lesions may occupy but a small part of one lung, and usually near the summit.

Kingston Fowler has investigated the question of the points of election and paths of distribution of the lesions in chronic phthisis, and has found that the primary lesion is not, as a rule, at the summit of the upper lobe, but that it occurs from 1 to $1\frac{1}{2}$ inches (3.79 cm.) below this point and near the postero-external borders. Favored by normal respiration, the lesions advance downward, so that on physical examination the first evidences of disease are to be found posteriorly over the lower part of the supraspinous fossa, while anteriorly the early signs are met with immediately below the middle of the clavicle, extending along a line running about $1\frac{1}{2}$ inches (3.79 cm.) from the inner end of the second and third interspaces. The starting-point, though less frequently, may also be indicated by physical signs in the first and second interspaces below the outer third of the clavicle, with subsequent downward extension.

From personal observation of the post-mortem lesions of this disease, and from my studies at the bedside, I feel convinced that the initial lesion is frequently located anteriorly and near the apex, corresponding on the chest-walls to the clavicle and the supraclavicular spaces. This site has seemed to me to obtain more often on the right side than on the left. Kingsley has shown that when the lower lobe becomes involved the consolidation begins about $1\frac{1}{2}$ inches (3.79 cm.) below its apex posteriorly, and corresponding externally to a spot opposite the fifth dorsal spine. From this point it spreads downward and laterally in a line fol-

lowing the border of the scapula "when the hand is placed on the opposite scapula and the elbow rests above the level of the shoulder." The middle lobe on the right side is usually invaded by direct extension from the upper. The seat of primary infiltration may even be the lower lobe, but this is rare. Cole¹ has found lesions at the root to precede parenchymal changes.

The relative frequency of involvement of the two sides varies according to different authorities. A careful analysis of my records and those of other observers show that out of a total of 1236 cases 726 occurred on the left side and 510 on the right.

In all cases the primary lesions are due to *tuberculous infiltration*, which at first is confined to certain lobules, though it may later involve extensive areas of lung-tissue (*tuberculous broncho-pneumonia*.) In most instances the starting-point of the morbid changes is in the smaller bronchi and also, according to Payne, the inside of the alveoli. Soon the bronchioles and the corresponding air-cells become blocked with inflammatory products. These areas then undergo caseation and present the usual opaque, grayish-yellow appearance, a cross-section of these yellow nodules showing the central bronchus usually plugged with exudate and surrounded by caseous matter. Softening and sometimes complete liquefaction, with expectoration or absorption of the altered morbid products, may take place, and this disintegration is associated with *ulceration* in the wall of the bronchus, consequent upon secondary pyogenic infection, and a resulting formation of small *cavities*. Ulcers may form in the bronchioles before necrotic processes supervene, and they are generally shallow, with sharply-defined edges. Recovery may ensue as the result of *calcification* with encapsulation of the cheesy masses, or the affected area may undergo *fibroid transformation*—a conservative process and one that may lead to actual cure. It often happens, however, that old and apparently healed tuberculous lesions undergo ulceration, when the calcareous masses (pulmonary calculi) may be dislodged and expectorated, and the more rapidly the caseous masses are formed the more liable are they to softening. Surrounding the healed areas the tissue may be the seat of atelectasis, though more often of emphysema. Destruction of lung-tissue also results from interstitial inflammation with the formation of new connective tissue, the latter in turn compressing and finally obliterating the alveoli.

Cavities (*Vomicæ*).—These result chiefly from progressive necrosis and ulceration. They are formed mostly by dilatation of the bronchi, whose walls are tuberculous and suppurating. But they may also arise independently of the bronchi. Cavities vary largely in number, size, and form. They are often multiple, though usually not far removed from one another, and unite as they increase in size. In this way large cavities, with irregular walls, involving the whole of one lobe and even an entire lung (except the extreme anterior margin), may be formed, and small pockets connecting with the bronchus may thus originate.

Vomicæ may be classified as (1) progressive and (2) non-progressive.

(1) The **progressive** are divisible into (a) New cavities and (b) Old cavities.

(a) *New cavities* have soft, necrotic, friable walls so long as the de-

¹ *Amer. Jour. Med. Sciences*, July, 1910.

structive processes are rapidly progressing, and the same state of things prevails in the cavities of acute phthisis. They may develop near a healed focus or near old cavities with limiting walls, and when situated near the periphery of the lung they may rupture into the pleura, causing pneumothorax.

(b) *Old cavities*, as a rule, have sharply-defined walls that vary considerably in thickness. At first they consist of a fibro-vascular zone, which has an inner suppurating surface; subsequently the lining of this zone is converted into an exfoliating membrane. The contents of vomicæ are muco-purulent or purulent, and often consist of a shreddy and sometimes a bloody fluid. Rarely they are gangrenous. Cavities also contain tubercle bacilli and other micro-organisms. Percy Kidd has studied the question of the relation of tubercle bacilli to tuberculous pulmonary lesions, and states that they are invariably present in newly-developed tubercles and fresh cavities, but frequently absent in old nodules. Trabeculæ composed of blood-vessels and remnants of pulmonary tissue often traverse the cavities. In old cavities excavation may be complete, not a vestige of normal or diseased tissue remaining in them, though the blood-vessels, many of which are beaded by small aneurysmal dilatations along their course, are the last to disappear. Their removal is effected by an obliterating inflammation. Rupture of these miliary aneurysms or the erosion of a large vessel gives rise to copious hemoptysis. Cavities having dense walls may also increase in size by encroaching upon the surrounding tissue, huge cavities often having thin, tense walls. But, wherever situated, they usually begin toward the summit of the upper lobe. Another common seat is the mid-dorsal region.

(2) **Non-progressive Cavities.**—Quiescent cavities are usually small, though variable in size, according to the stage at which the process of contraction is arrested. Medium-sized and large vomicæ do not become totally occluded. They may be multiple, though more often perhaps single, and associated with them may be observed dense, fibrous nodules representing healed foci. Their interior may be lined with a smooth, cuticular structure resembling mucous membrane.

Interstitial Pneumonia.—In the course of chronic phthisis interstitial inflammation of two sorts will most probably arise: (a) A consolidation excited by the tubercle bacilli themselves, and hence manifesting a *destructive* tendency; (b) A slowly-developed *interstitial pneumonia* which aims at *arresting* the progress of the affection. It develops in close proximity to caseous masses and around cavities. The new connective tissue thus formed in obedience to the well-known pathologic law tends to contract secondarily, and thus vomicæ are often partly, though seldom entirely, obliterated. The shrinking of the connective tissue may also result in compression, and finally in the destruction of pulmonary tissue, just as in a tuberculous inflammation. The process in this instance, however, is on the whole conservative and reparative.

Disseminated Tuberculosis.—*Miliary Tubercles.*—This form has for its chief characteristic miliary tubercles, which are scattered not only about the tuberculous area, but also throughout the rest of the lung, and usually in the lower lobe. Most of the tubercles undergo fibroid or fibro-caseous change. These minute, hard gray or grayish-yellow

nodules vary in size from a mustard-seed to that of a pea, and lung-tissue that is more or less studded with chronic miliary tubercles is apt to look pale, while the surrounding air-cells are *emphysematous*. The condition may lead to pneumonia, and the whole aspect then becomes altered. Here, as before described, fusion of miliary tubercles results in larger masses which become caseous, and hence the method of cavity-formation is identical with that observed in tuberculous broncho-pneumonia. In the disseminated form tubercles may also be found in many other organs than those indicated (pleura, trachea, larynx, bronchial and other lymphatic glands, peritoneum, spleen, kidneys, liver, brain, mucosa, testes, etc.).

Lesions of the Pleura.—This membrane is hyperemic and coated with fibrinous exudation coextensively with the affection of the parts in chronic ulcerative phthisis. The pleural membranes are only more or less thickened by organized adhesions, but in the latter and also in the pleura tubercles or cheesy masses may be found. Simple and other forms of pleurisy are met—sero-fibrinous, purulent, and hemorrhagic.

Lesions of the Bronchial Glands.—At first these are enlarged and edematous, containing tubercles, and later they present foci which often undergo purulent disintegration and sometimes calcification. Other lymphatic glands than these may be affected (mesenteric, etc.).

Lesions of the Larynx.—The larynx is frequently the seat of tuberculous infiltration and ulceration, particularly in certain parts, such as the vocal cords, posterior wall, and ary-epiglottidean folds.

Lesions of the Heart.—Tuberculous endocarditis is present in about 5 per cent. of the cases, and congenital stenosis of the pulmonary orifice is noted in not a few instances (Chevers). The right heart is often hypertrophied or dilated.

Other organs may present lesions in chronic phthisis, and these will be spoken of in connection with the clinical history.

Tuberculosis of the intestinal canal is a common though late lesion.

Amyloid degeneration of certain organs is a not unusual secondary event, especially of the kidneys, liver, spleen, and intestinal mucosa. Enlargement of the liver due to *fatty infiltration* is sometimes noted.

Clinical History.—The modes of invasion are quite diverse, but with few exceptions the onset is either (1) gradual or (2) abrupt, and, as a rule, the health has been previously undermined for a longer or shorter period.

(1) **Gradual Onset.**—(a) The disease often originates in a manner similar to *ordinary bronchitis*, and the symptoms of pleurisy are sometimes associated. Tuberculous bronchial affections often follow certain acute infectious diseases—influenza, typhoid, measles, whooping-cough—and in this form are rarely curable. The *physical signs* may be negative for some time, and then appear in the apex region, and the most characteristic grouping of physical signs during the incipient stage may be thus summarized: “Lagging” or defective expansion, as noted on inspection and palpation, a localized increase in the tactile fremitus, slightly impaired percussion-resonance, enfeeblement of the normal vesicular murmur, with (at a later period) prolongation and sharpening of the expiration. The fact that the lesions are commonly detectable in the suprascapular fossa must be remembered. At this period obvious *constitutional disturbances* are present (debility, fever).

(b) *Onset with Pleurisy.*—This may be sudden, as in an acute pleurisy with effusion, but often the latter condition develops insidiously. Of 90 cases of pleurisy with effusion, one-third terminated in chronic phthisis (Bowditch). It may begin as a dry pleurisy at the apex, either anteriorly or posteriorly, or the evidence of pleurisy may be associated with the more common bronchitic onset.

(c) *With Gastro-intestinal Symptoms.*—There is impaired digestion, and soon the patient becomes anemic, loses flesh, and is debilitated. Later, the first indications of pulmonary tuberculosis develop in the lungs. Close scrutiny of the data entering into the early history of cases of pulmonary tuberculosis usually reveals some perversion of the general health before distinctive pulmonary phenomena arise.

(d) *With indefinite peritoneal symptoms,* lasting for months or years.

(e) *With Laryngeal Symptoms.*—This is a rare form. It begins with hoarseness, more or less aphonia, and considerable cough; there is also a slight mucopurulent expectoration. Laryngoscopic examinations may detect tuberculosis of the organ, and tubercle bacilli may be found in the sputum before involvement of the lungs is discoverable.

(2) *Cases with Abrupt Onset.*—(a) The most important group under this category is heralded by the symptoms and signs of *pneumonia*, more commonly of the lobular variety. As compared with lobar pneumonias, these present peculiar features: the fever is irregular, the expectoration is more abundant, is blood-stained, and contains bacilli. The signs are usually located in the apical region. Resolution may occur, but recovery is not complete, and the condition may pass into chronic phthisis.

(b) *Onset with Fever.*—Chills and fever generally arise in the advanced stage of pulmonary tuberculosis, but these symptoms may also initiate the attack. There is no mistake in diagnosis more commonly made in malarial regions than to ascribe such cases to paludism.

(c) *With Hemoptysis.*—This symptom may invite attention to lung trouble. Müller states that hemoptysis was an early symptom in 170 of the 875 patients at the Davos German Sanatorium, and was twice as frequent in the male as in the female. The amount of blood lost is either considerable or repeated slight hemorrhages occur. In a great proportion of cases the clinical picture of incipient pulmonary tuberculosis is revealed, pursuing its accustomed course immediately after the occurrence of the hemorrhage. The physical signs may be latent for a time, and, while they are usually located in the subapical area, they may assume the guise of a pleurisy in the infrascapular region. A slight tuberculous lesion is present in these cases preceding the occurrence of the hemorrhage.

The **symptoms** are (1) *local* and (2) *general*.

(1) *Local.*—(a) *Pain.*—This is absent in many cases of chronic phthisis and in others it may be moderately severe. It is seated usually at the base, laterally or anteriorly, and not rarely there is pain of a lancinating character in the interscapular region in the early stages of the affection. This symptom is of diagnostic worth only after other forms of pain (rheumatic, neuralgic) have been excluded. The most common cause of pain is pleuritis, with or without pleuritic adhesions; it is increased on deep breathing and coughing. Intercostal neuralgia and pleurodynic stitches may also develop soon or late. Tenderness on

pressure with the right forefinger (algeoscopy), which causes the patient to exclaim or make a grimace, or merely a contraction in adjoining muscles, was present in 77.9 per cent. of 200 cases studied by Francke, while only one-third of these patients complained of spontaneous pain.

(b) *The Cough*.—This may be looked upon as an essential feature, though in a few instances it may be slight or even wanting throughout. Its severity bears no constant relation to the extent of the pulmonary lesions, but rather to the degree of sensitiveness of the patient. It is dry and hacking at the beginning, and, if the larynx be involved, the cough is marked and of a hoarse quality. It is most pronounced at certain periods of the day—viz., on lying down at night and on awakening from sleep. Paroxysms may occur after meals and induce vomiting. The cough is at times distressing and debilitating in its effects.

(c) *Expectoration*.—At the beginning the sputum is scanty and mucoid, rarely hemorrhagic, or it may be merely streaked with blood; later it may become muco-purulent, and the appearance of small gray or grayish-yellow flocculi first suggests the nature of the affection. With the onset of the stage of cavity-formation the sputum becomes more abundant and more distinctly purulent, and, after the formation of cavities of any size, airless, opaque, and nummular (coin-shaped) masses are expectorated. The latter are greenish-gray or greenish-yellow in color, and sink rapidly when discharged into water. They are often mingled with more or less bronchial secretion, and are sometimes observed in pure bronchitis. They may even be absent, and the expectoration be merely purulent. The opening of a fresh cavity may be followed by very free expectoration. The sputum is sometimes fetid, and exceptionally it is horribly offensive, varying greatly in amount in different cases and at different stages of the disease. In certain cases it is absent throughout the greater portion of their course, and is especially apt to be slight in children and old people. In such instances it may be impossible to collect sufficient sputum to examine for bacilli.

Microscopic examination discovers alveolar epithelium (particularly in the earlier stages), pus-cells, blood, fat-globules, elastic fibers, and *tubercle bacilli*, the detection of the latter being the most important factor in the diagnosis. It may be safely stated that the finding of bacilli in the sputum is *prima facie* evidence of chronic phthisis; on the other hand, however, their absence in the early stage does not exclude the disease. It is often needful to make repeated and delicate examinations of the sputa. It is also of the utmost importance to select for examination the small grayish masses that are usually to be found, since they early contain the bacilli. In tuberculosis in the aged tubercle bacilli are not always detectable in the sputum.

Method of Examining the Sputum.—"A small amount of the purulent portion of the sputum is spread in a thin and uniform layer on a perfectly clear cover-glass by means of forceps, needles, or the Ohse, which must previously be held a moment in the flame of a Bunsen burner or a spirit lamp, or by pressing a small amount of sputum between two cover-glasses, then sliding them apart. It is then dried in the air, or more quickly by holding the cover-glass with forceps some distance above the

flame of a burner or lamp. Finally, it is to be passed three or four times through the flame, and so 'fixed' (Musser). Brown and Smith¹ recommend antiformin for the cultivation of tubercle bacilli directly from, and also to digest, the sputum.

The preparation may be stained with carbol fuchsin (basic fuchsin 1, alcohol 10, 5 per cent. solution of carbolic acid 90), either by dropping a few drops of the stain on the smeared side of the cover-glass and holding it above the flame until it steams, or by floating its face downward upon a watch-crystal containing the solution. It must then be decolorized either with a 30 per cent. solution of nitric acid, allowing it to remain until the red color has entirely disappeared (about fifteen seconds), and then washing and counter-staining with methylene-blue, or with Gabbett's solution (methylene-blue 2 gm., sulphuric acid 25 c.cm., water 75 c.cm.), in which it must remain until the red color has been replaced by a faint blue (thirty seconds or more). Instead of carbol-fuchsin, anilin gentian violet may be employed (add a saturated alcoholic solution of gentian violet to a filtered saturated solution of anilin until a metallic luster appears on the surface). The specimen may lie either several hours in a cold solution or a few minutes in one that is steaming. Decolorize with the nitric-acid solution ($\frac{1}{2}$ per cent.), and counterstain with rubin or a saturated aqueous solution of Bismarck brown. It is often much simpler to smear the sputum directly upon the slide, and then examine, when stained, without the intervention of a cover-glass. A much larger amount of sputum can thus be prepared.

FIG. 21.—Elastic fibers (after Strümpell).

In the microscopic examination use a $\frac{1}{12}$ -inch (2.11 mm.) oil-immersion lens and Abbé condenser. If carbol-fuchsin has been used in staining for the bacilli, and methylene-blue as a contrast, the former will be found as red rods in a blue field (background), while if gentian-violet has been used, the tubercle bacilli appear as dark violet rods, with all other bodies brown, if Bismarck brown is used for the contrast stain. There may be visible in the field a few bacilli only, particularly during the early part of the case. In the stage of cavity their number is usually increased, and sometimes they are quite numerous.

The demonstration of *elastic fibers* is also an important aid to diagnosis. Fenwick's method is the following: Boil the sputum with an equal quantity of a solution of caustic soda (gr. xv-3j—0.972-32.0); pour the product into a conical glass and fill with cold water. The sediment is subsequently examined with care for elastic fibers.

The *form* and *appearance* of the elastic threads differ according to

¹ *Jour. Med. Research*, Boston, 1910, xxii., 517.

their special source. If they come from the alveoli, there is an interlacing of the fibers which may preserve the globular contour of the air-cells. If they come from the blood-vessels, they are single and elongated, or two or three of the fibers may be arranged side by side. Elastic tissue derived from the bronchi has a similar appearance.

The presence of elastic fibers furnishes incontestible proof that destruction of lung-tissue has taken place. To show that this loss of structure, however, is due to tuberculosis, we must exclude abscess (rare) and gangrene of the lungs—diseases in which it also occurs.

(d) *Hemoptysis*.—This symptom of phthisis will be spoken of under Diseases of the Lungs, but its importance as a diagnostic feature of this disease makes special reference to it here absolutely necessary. It is present in the majority of cases. Gabrilowisch¹ found that of 380 patients 213, or 56 per cent., had hemoptysis. The sputum may be merely blood-stained, or the hemorrhage may be excessive and prove rapidly fatal, though hemoptysis is rarely the direct cause of death in tuberculosis. Slight hemorrhages are usually produced by mere hyperemia, and are most apt to occur during the early stages; while severe bleedings are produced by the erosion of a blood-vessel or rupture of a small aneurysm, and are most prone to occur during the stage of cavity. In certain cases hemoptysis is frequent.

A third or capillary form of hemorrhage may occur in phthisis with cavity-formation, and in this variety, which is of a rather frequent occurrence, the purulent sputum is uniformly stained with blood. It may also be nummular, but presents a reddish-brown or chocolate color. The *exciting cause* is seldom obvious, though in not a few instances aggravation of the cough, and in others great mental excitement, would appear to excite bleedings. Slight hemorrhages often, and severe ones rarely, afford more or less relief to the pulmonary condition. On the other hand, severe bleedings usually exert an unfavorable influence, being followed by debility and anemia. Moreover, in numerous cases hemoptysis is followed by a more rapid extension of the local lesions, with corresponding aggravation of the local and general manifestations. The fact remains, however, that the effect of severe hemoptysis upon the progress of chronic phthisis is by no means always untoward. In a case of my own there occurred periodically copious spontaneous bleedings (in spring and fall) for three years, which were as regularly followed by marked improvement for a period of three or four months. The physical signs of phthisis then developed. In a large number of cases of pulmonary tuberculosis the transition from warm to cold or cold to warm seasons corresponds with increased cough, hence with increased pressure in the pulmonary circulation; and so bleeding is also favored, particularly in those having a hemorrhagic tendency.

(e) *Dyspnea* is present, but is not a marked feature, as a rule, despite advanced pulmonary lesions. Perhaps the chief reasons for a lessened demand for oxygen on the part of the system are—first, the slow and gradual manner in which the lesions develop; and second, the pronounced bodily wasting. The *respirations*, however, are moderately increased in rate, averaging from 20 to 30 per minute, and this compensates admirably for the diminished breathing-space. The dyspnea may

¹ *Berliner klinische Wochenschrift*, Jan. 2, 1899.

be greatly intensified, however, as the result of intercurrent pneumonia, pleurisy, active exertion, or great mental excitement, and toward the close of fatal cases the most intense dyspnea may be manifested.

Physical Signs in the Stage of Consolidation.—*Inspection* gives most important results. The paralytic or phthisical thorax is generally presented to view. It is flat, particularly the upper half; the intercostal spaces are wide; the ribs slope at a sharp angle from the sternum, making the epigastric angle acute and producing elongation of the chest. The same sharp inclination downward from the vertebral column is observed laterally and posteriorly. The angle of Louis is prominent, and the depressions (supra- and infraclavicular, intercostal) are deepened, the costal cartilages being often prominent and the sternum, particularly in the lower part, sometimes much depressed or even concave (funnel-breast). The scapulæ stand out prominently and may be distinctly winged. A second type of paralytic thorax is narrow and long. Pulmonary tuberculosis may, however, arise in chests of apparently normal build. The paralytic thorax is often a resultant of developed phthisis. In subjects of obesity the phthisical thorax may be concealed. The deformity due to occupation, as leaning over a desk, may ape the paralytic chest, and, finally, it may be the result of extreme emaciation. With the development of phthisis the depressions of the side affected are relatively deeper, while the clavicle often stands out prominently.

Defective expansion is observed early, and usually at the apex of the side first affected; subsequently this may be more general, and finally bilateral. To note the motions of respiration with precision the examiner should occupy a position exactly in front of the median line of the patient's body. The difference in the movement of the two sides often becomes more apparent on deep respiration than on quiet breathing, and while at rest the respirations are almost normal, but exertion decidedly increases their frequency.

Palpation.—Testing the expansion by palpation gives better relative results than does inspection. To determine the comparative movements of the apices the extended hands should be so placed (by allowing them to diverge below) that the tips of the fingers touch the lower border of the clavicle, and then the patient should be asked to breathe deeply, though slowly. The expansion in the supraclavicular spaces is tested by standing behind the patient and using the tips of the fingers, or by allowing the two first fingers of each hand to pass parallel with the clavicles. In this way "lagging" over the apex will be the first symptom recognized, and may for some time be the only one. Palpation of the vagus nerve on the affected side elicits pain (Mays).

Tactile fremitus is early increased with oncoming consolidation, though it is normally more marked at the right than at the left apex. If there be thickening of the pleura, however, it is diminished, and if there be pleural effusion it may be absent.

Mensuration.—The difference between the measurement of the chest in inspiration and expiration in any person of average health should be not less than three inches, and a difference below two and a half inches points strongly to tuberculosis. The data thus gained are more important than the shape of the *thorax*.

Percussion.—Resonance is deadened more and more as consoli-

dation progresses. If the consolidated areas are minute, however, the percussion-note may be unchanged, and as the air-cells surrounding the latter are often emphysematous and relaxed, it may be somewhat tympanitic. The tympanitic sound and deadness may be intermingled, giving rise to the so-called tympanitic deadened sound. Slight dulness is, as a rule, noted first below the clavicle, though in not a few cases it is first detected above the clavicle. Impaired resonance, however, may be detected, first, in the supraspinous fossa, and less frequently in the interscapular space if the subject is not too stout, though slight dulness in the absence of other signs has little diagnostic value. The corresponding regions of the two sides must be compared during a held inspiration and also during a held expiration. The degree of dulness can sometimes be better estimated by comparing the apical note with that obtained lower down on the same side, allowing for the normal topographic differences of intensity. The latter method is especially applicable to cases in which both apices are involved. Light and single percussion blows must be used. As the lung-tissue becomes airless throughout an area of considerable size the note is deadened, until dulness is heard; finally, with extensive consolidation, the note may be wooden and the feeling of resistance increased.

Auscultation.—The vesicular breathing may be sharpened, owing to narrowing of the smaller bronchi, but more often perhaps it is diminished by the swelling and secretion. The corresponding regions on the two sides must be compared—first during quiet, and then deep breathing—and it should be remembered that prolonged expiration is an early and important diagnostic sign, at first being somewhat sharpened, and later distinctly bronchial. Tuberculous bronchitis may cause interrupted or jerking inspiration at the apex with or without crepitant râles. If heard elsewhere, it has small value. With lobular consolidation at different points in the region affected, the conditions favor the transmission of the bronchial sounds, but these are toned down by the remaining intact air-cells; hence there is “transition” or bronchovesicular breathing. With complete consolidation pure bronchial breathing is audible, and with the latter two forms of breathing crepitant or subcrepitant râles are heard. A clicking râle, although not common, is an almost conclusive indication when observed. Sometimes the first râles which accompany expiration have a low whistling sound; with liquefaction they become more moist, are louder (somewhat ringing), and often bubbling, and may be heard on inspiration and expiration. If scanty, they may be audible on inspiration only; they are increased by coughing. If the moist crepitant and subcrepitant râles, often due to concurrent bronchitis, be very numerous, the breath-sounds will be obscured, but after free expectoration their quality becomes appreciable.

Pleuritic friction-sounds may be heard, due to accompanying pleuritis sicca, and these may be audible before the bronchial râles reveal the disease. Friction-sounds and râles often occur together. *Pleuropericardial friction* is present when the “lappet” of lung over the heart is affected, while clicking râles, occasioned by the heart’s systole, are audible when the same area is pneumonic. The vocal resonance increases with the progress of the consolidation, and when the latter is complete, *bronchophony* (rarely *pectoriloquy*) is present. In the subclavian arteries a systolic murmur is not uncommonly heard, the latter being supposed to be due to pressure exerted by the thickened pleura upon these vessels.

Physical Signs of Cavity.—*Inspection* shows a more marked retraction and a more decided lack of local motion than during the previous stage. The degree of shrinking is proportional with the extent of fibrous-tissue formation.

Palpation corroborates inspection as to lack of motion, and gives increased tactile fremitus if the cavity connects with an open bronchus and if it contains but little secretion. Excessive secretion interferes with conduction of sound.

Percussion.—Resonance is generally more or less impaired in consequence of the consolidation of the surrounding lung-tissue. The note may be somewhat tympanitic, but varies with the position of the cavities, the amount of fluid secretion contained by them, the condition of their walls, and the vibratory capacity both of the latter and of the individual thorax. Cavities of the size of a walnut situated in the apices usually give a distinctly tympanitic note, while cavities of the same dimensions, or even larger, in the lower portion of the lung do not. The metallic tone is especially noticeable over large cavities with smooth walls. The tympanitic sound may be deadened by closure of the connecting bronchus and by temporary filling of the cavities with secretion, and, again, if they are surrounded by thickened lung-tissue or by a large thickened pleura, there may be impaired resonance or absolute dulness even. Certain *special conditions* change the tympanitic sound over a cavity. Thus the note will be louder and exalted in pitch when the mouth is opened wide, and lowered when the mouth is closed (Wintrich's sign), there being dulness when the mouth is closed and tympanitic resonance when the mouth is open. If the cavity communicates freely with the bronchus, a tympanitic note may change in pitch with change in posture (Gerhardt's change of sound). If the patient changes from the dorsal to the upright position, resonance may give way to more or less flatness over the lower portion of the cavity, since the fluid contents of the latter are thus brought into contact with the chest-wall; this, although an almost certain sign of a cavity when present, is exceedingly rare. The so-called cracked-pot sound is often elicited over large parietal cavities with thin walls; but, since it also occurs in many other pathologic conditions, its diagnostic significance is subordinate. There may even be normal resonance if the cavity is covered by a layer of unaffected air-cells of considerable thickness.

Auscultation over small vomicæ with lax walls reveals *cavernous* (low-pitched) breathing, while over large cavities with tense walls (if parietal and communicating with a tracheo-bronchial column of air) it gives amphoric (higher-pitched) respiration. Moist râles (bubbling and gurgling, according to the consistency of the secretion) may be present, and these correspond in the main to the amphoric breathing, hence being heard most frequently over large, smooth-walled and peripherally-located cavities. The gurgling and slushing sounds caused by the air bubbling through the secretion in a cavity are always intensified by coughing.

The sounds of falling drops (metallic tinkling) may be heard over large vomicæ with tense, smooth walls containing thin secretion. *Pectoriloquy* and *amphoric whispers* are the vocal sounds heard over huge cavities. Whispering pectoriloquy was present in 55 out of 58 cases at

the Phipps Institute, but other pathologic conditions may cause this sign, "notably consolidation about a bronchus" (Landis).

FIG. 22.—1, Small cavity near periphery, with thick relaxed walls, containing secretion and communicating with a bronchus (*vide* subjoined table). 2, Large parietal cavity, with thin, tense, smooth walls, communicating with a bronchus (*vide* table).

Physical Signs.

- (a) Percussion-deadness on a strong blow, mere impairment of resonance on a light blow; Wintrich's interrupted change of sound, detectable only when patient is upright.
- (b) On auscultation low-pitched cavernous (hollow) breathing; gurgling râles.
- (c) Pectoriloquy indistinct, owing to small size of cavity and the contained fluid.

Physical Signs.

- (a) Amphoric percussion-resonance, cracked-pot sound, and Wintrich's change of sound.
- (b) On auscultation, high-pitched amphoric (musical) respiration and metallic râles.
- (c) Amphoric (musical) voice and amphoric whisper.

General Symptoms.—(a) **Fever.**—Whilst the disease is progressing fever is a constant, significant, and, it may be, the earliest, symptom. If a two-hourly record be kept for a few days, from time to time an accurate conception of the course and type of the fever can be formed. In the first and middle stages the highest temperature occurs about 4 or 5 P. M., the lowest about 4 or 5 A. M. The fever may be continuous, remitting, or intermitting, and in a general way these types, in the order named, correspond to the stages of tuberculization, softening, and cavity-formation. Modified types, due to the fact that the lesions may simultaneously represent different stages, are also observed. Apyrexial periods are met with in the early as well as the late stages of chronic phthisis, and indicate cessation of the processes of tuberculization and caseation.

A *continued fever* is most apt to be met with during the initial period, the evening temperature sometimes registering but a degree higher than the morning. A similar curve may be presented at any later time if acute pneumonia supervene, though it is to be recollected that the remissions in such cases are usually greater than in primary lobar pneumonia.

A *remittent fever* is more common than the preceding type. It may be present from the start, but is oftener seen in the middle and less frequently in the advanced stages. It points to softening (see Fig. 23).

An *intermittent fever* is also frequent, and is invariably associated with cavity formation. The temperature may be intermittent from the

FIG. 23.—Temperature-chart of a case of phthisis. Quiescent cavity in right apex, and commencing excavation in left apex. Robert G—, aged 21 years; dyer.

start, suggesting malaria to the unguarded; but it is due to sepsis, the temperature rising during the day, beginning usually shortly before

FIG. 24.—Temperature-chart of a case of phthisis. Cavity in left apex, giving cracked-pot sound, Wintrich's sign, etc. George C—, aged 22 years; glass-worker.

noon, and reaching its maximum at from 5 to 8 P. M. It now falls slowly until about 4 or 5 A. M., and then rapidly reaches the minimum—a sub-

normal point—usually at from 6 to 10 A. M. For a considerable portion of every twenty-four hours the temperature may be below the normal (see Fig. 24), sometimes dropping as low as 95° F. (35° C.).

(b) **Night-sweats** occur in a large majority of cases. They may appear during any part of the course of phthisis, though most apt to occur and be most marked during the process of cavity-formation; they show themselves in the early morning hours simultaneously with the rapid decline in the temperature, and may appear during sleep at any period of the day. They may be light and limited to the neck and upper portion of the thorax; on the other hand, they are often excessive, saturating the bed-clothes and inducing great exhaustion. The drenching sweats are dependent partly upon the fever and partly upon the existing weakness, though slight exertion may also engender free perspiration.

(c) **Emaciation** occupies a prominent place in the symptomatology, the muscular and fatty tissues being involved to an equal degree (Strümpell); the extremities and soft parts of the thorax are most affected. An exalted grade of emaciation, however, may be present at an early period, and in such cases it may be assumed that the thinness of flesh was a precursory state. In nearly all cases an extreme degree of emaciation, reducing the patient to a slightly covered skeleton, is reached before the end. The causes of emaciation are chiefly the persistent fever, the loss of appetite, and the feeble digestive and assimilative powers. It is an almost invariable rule that during the afebrile periods, associated as they are with improved appetite and digestion, the patient gains in flesh and strength. Unilateral atrophy of the muscles of the chest may be observed.

(d) The **pulse** is increased in frequency, is of good volume and regular in rhythm, though of low tension (soft). When suppurative fever sets in it becomes frequent and compressible, and the capillary pulse is often observed; rarely venous pulsation is seen in the hands.

(e) **Anemia** is one of the symptoms evidencing impaired nutrition. It is often associated with an afternoon rise of temperature, impaired digestion, and loss of flesh and strength (chloro-anemia). The objective changes pointing to anemia are pronounced (pallor of lips, visible mucous membranes, and skin). The *blood* presents nothing characteristic. In the early stage it may be chlorotic in type, the hemoglobin being decidedly deficient; but when there are cavity formation and hectic fever, considerable leukocytosis, as many as 50,000 leukocytes per cubic millimeter, may be observed. The differential count shows a great excess of the polymorphonuclear cells. Early lymphocytosis, however, may be of considerable diagnostic value. The condition is due to secondary infection by the pus-forming organisms. Absence of eosinophile cells would appear to be an unfavorable prognostic sign, while an increase indicates a tendency to arrest the progress of the disease (Swan). Tubercle bacilli cannot, as a rule, be found in the circulating blood (Ravenal and Smith).

General debility is complained of in all cases, and is progressive.

Symptoms and Complications Presented by Other Organs.—(a) **The Heart.**—With retraction of the upper lobe of the left lung the area of the heart's impulse is obviously increased, particularly upward, so that pulsation may be visible in the fourth, third, and even second interspaces, near the sternum, while the normal apex-beat may be wanting. The physical signs noted may be rarely those of displacement of the heart to the right, while the necropsy may show the heart to be in its normal posi-

tion. Functional murmurs both at the apex and at the pulmonary orifices are often audible. In about 7 per cent. of the cases with murmurs, mitral regurgitation, dependent on weakness of the heart muscles, was diagnosed.¹ Disease of the tricuspid segments is not infrequent in phthisis, and pulmonary stenosis predisposes to the latter disease. Conversely, there is perfect agreement among writers that left-sided valvular heart disease has a retarding influence upon the progress of chronic phthisis. In cases in which the valve lesions and the compensatory hypertrophy are proportional, a prognosis for an unusual length of days can be ventured, but "when this harmonious balance is disturbed an early fatal termination may be expected, principally from the cardiac complaints."² In combined cases dyspnea is more pronounced and hemoptysis a more common initial symptom than in non-cardiac forms.

(b) **Gastro-intestinal Tract.**—The *tongue* may be furred; more often it and the mouth and throat are red, showing increased irritability. The *pharynx* may be the seat of tuberculous lesions, which may interfere greatly with deglutition—*aphthous ulcers, thrush*. The appetite is impaired or lost; thirst is annoying and the symptoms of chronic gastritis often obtain. A catarrhal ulceration and dilatation may be associated conditions. Vomiting may be troublesome during the later stages. A study of the gastric secretion gives variable results, there being an early hyperacidity, while later the secretion is subacid. Croner found normal motility present in the early stages. The *causes* of gastric symptoms are not clear. The mucosa is the seat of venous engorgement, and thus occasions the catarrhal changes that are present in many instances. Anatomic changes may be absent.

The *intestinal symptoms* are important. During the early stage constipation is a frequent condition. Diarrhea is prone to appear at an advanced period, and may pursue an intermittent course. Occasionally it alternates with periods of "hectic fever," and late in the affection a watery discharge may develop (*colliquative diarrhea*). The intestinal lesions are of three sorts: (a) *catarrhal*, (b) *ulcerative*, and (c) *amyloid*. These often arise in the order enumerated, but may be combined in various ways. Hemorrhoids and anal fistulæ are among the complications.

(c) **Genito-urinary Organs.**—There is frequently an albuminuria that may either be febrile or due to chronic nephritis (*productive and non-productive*). *Chronic nephritis* is usually a late development; it gives rise to albuminuria, tube-casts in the urine, and dropsy. *Amyloid changes* may set in toward the close with their characteristic symptoms. Tuberculous *pyelitis* and *cystitis*, with the appearance of pus and (rarely) blood in the urine, may develop. Hematuria may also result from temporary congestion. The testes may be implicated, and a routine inspection of these organs should not be neglected (Osler).

(d) **Cutaneous System.**—*Cyanosis* occurs, but, being of a moderate degree, it is often veiled by a decided pallor. The *cheeks* often wear a "hectic flush," and the skin, late in the affection, is apt to be dry, harsh, and scaly. Among the cutaneous appearances are pigmentary stains over the chest (*chloasmata phthisicora*) and brown stains (*pityriasis versicolor*). The *hair* over the chest often becomes gray; that of the head

¹ "A Study of Murmurs in Pulmonary Tuberculosis," *American Journal of the Medical Sciences*, June, 1910, by C. M. Montgomery.

² *Amer. Jour. Med. Sci.*, Jan., 1902, by the writer.

and beard, long and harsh. The *finger-ends* are often bulbous (clubbed), with incurved nails, though this is not peculiar to chronic phthisis, and cracking of the finger-nails is also often observed. Swelling of the upper eyelid has been noted as a symptom.

(e) **Nervous System.**—The mental attitude is characteristically hopeful and buoyant, even in the advanced stages. Hence the patients are readily encouraged by the unscrupulous to believe that their condition is improving, despite the steadily unfavorable progress of the disease, and, indeed, they may be in an utterly helpless state, and yet confidently expect to recover. The *cerebral symptoms* are rarely marked, and the mind, as a rule, is exceptionally clear. Tuberculous meningitis and meningo-encephalitis may develop near the close. Focal lesions, due to the presence of tubercles, may produce forms of paralysis (aphasia, hemiplegia) according to their location. Rarely peripheral neuritis (usually an extensor paralysis of the leg) and insanity are observed.

(f) **Chest-muscles and Mammary Glands.**—The former are abnormally irritable, and sometimes even painful on percussion, and the mammary gland is in rare instances hypertrophied, males suffering most; but, as pointed out by Allot, the affection is a chronic non-tuberculous mammitis.

Diagnosis.—The early recognition of chronic pulmonary tuberculosis often tests severely the diagnostic acumen of the physician. The general and local symptoms, including the physical signs, may afford merely a strong suspicion of the existence of phthisis, and in such instances repeated examinations of the sputum for the bacilli are imperative, and only when they are found is the diagnosis set at rest. Repeated staining of the sputum may be necessary for the detection of tubercle bacilli. It is also desirable to determine whether they are constantly present by re-examinations at intervals. There are cases in which the physical signs are obvious, yet the bacilli are either not detectable or only so after several examinations. An absence of the bacilli, however, does not justify a denial of the existence of phthisis, and is of little negative value. Philip and Porter conclude that tubercle bacilli are almost constantly present in the stools, whether the patient be expectorating bacilli or not. The symptoms of greatest diagnostic value are cough, expectoration, fever, progressive emaciation, and the constant presence of certain physical signs in the subapical region on one side (flattening of the chest, defective expansion, slight deadening of the percussion-note, enfeeblement of the vesicular murmur, prolonged expiration, with or without adventitious sounds). Francis H. Williams has produced skiagraphs that show the presence of tuberculous deposits and pleuritic exudates, and these may, at times, give the earliest positive information in regard to these conditions.¹ More reliable knowledge can be gained in the initial stage, if the lesions be deep seated, by the fluoroscope than by practising the physical signs. Thus enlarged bronchial glands and peribronchial infiltration are detectable.

The *tuberculin-test* is warmly commended by Trudeau, Otis, Klebs, and others. It is fairly accurate, and out of a total of 1470 injections in dubious cases, 71.9 per cent. reacted positively.² Its use should be

¹ For illustrative cases see "Diagnosis and Treatment of Prebacillary Stage of Pulmonary Tuberculosis," *The Journal of the Amer. Med. Assoc.*, Jan. 12, 1901, by the writer.

² "The Value of the Tuberculin-test in the Diagnosis of Pulmonary Tuberculosis," by the writer, *New York Medical Journal*, June 23, 1900.

limited to patients who have symptoms and signs of this disease, since latent tuberculosis gives the reaction, after other methods of diagnosis have failed us, and medium-sized initial doses are to be employed. A positive reaction demands an elevation of temperature to 101° F., and this rise usually occurs within twenty-four hours, but it may be delayed until thirty-six or even forty-eight hours. The possibility of reaction occurring in cases of syphilis, leprosy, chlorosis, hysteria, actinomycosis, and other affections will not lead to error if it is noted that such reactions are less intense. Calmette's ophthalmic reaction, which consists in dropping 1 to 2 minims of a 0.5 to 1 per cent. solution of tuberculin into the eye, produces hyperemia of the conjunctiva (at times actual conjunctivitis) in from three or four to twenty-four hours without constitutional disturbance. The symptoms subside in from twenty-four to forty-eight hours. Von Pirquet applies the tuberculin with gentle friction to the slightly abraded skin. If the patient be tuberculous, a reaction occurs in from 6 to 48 hours; this is especially valuable in the diagnosis of tuberculosis among children. The opsonin test is useful in the diagnosis of early tuberculosis, the index to the tubercle bacillus being very low or very high, the former suggesting predisposition, the latter showing infection against which the resisting powers are raised in defense (J. C. DaCosta). Airlong and Courmont¹ describe a method of serum diagnosis, but from the reported trials of other observers its results are too irregular to be of value. A slight rise of the evening temperature (99.6° F.—37.5° C. or over) is, if associated with any disturbance of health, an almost infallible diagnostic symptom. In the more advanced stages of phthisis the diagnosis is rarely difficult.

In the very early stage the local condition may be obscured by the symptoms of impaired digestion, loss of flesh and strength, fever, and pronounced anemia (chloro-anemia, *vide* p. 270; also *Modes of Onset*).

Differential Diagnosis.—*Bronchial catarrh* is with great difficulty discriminated from beginning phthisis. If the temperature is elevated from 2 to 5 P. M., and not at all or only slightly above the normal night temperature in the evening, the probabilities are greatly in favor of tuberculosis (Barlow). In bronchial catarrh there is no dulness, and moist râles, that vary in intensity from one day to another, are heard equally on both sides. From time to time râles may also be heard at the bases in bronchitis. In phthisis one apex is more involved than the other, the moist sounds not being heard equally low, and after repeated coughs with subsequent deep inspiration the râles are more apt to remain than in ordinary bronchitis. In phthisis, also, there is a gradual loss of flesh and strength, and repeated microscopic examination of the sputum will demonstrate the presence of the bacillus. A negative reaction, obtained repeatedly, from the Falk and Tedesco test,² is evidence that the disease process is limited to the bronchi, while a positive reaction indicates pulmonary involvement (tuberculosis). If *hemoptysis* be the first symptom observed, then all other causes for the spitting of blood

¹ *Deutsche med. Woch.*, Nov. 29, 1900.

² The test consists of the administration by mouth of salicylic acid or its salts. The salicylate is detected in the sputum by the addition of ferric chlorid, which produces a violet color, when the lung texture is involved, while no trace of salicylic acid can be found in the sputum in diseases limited to the bronchi, *e. g.*, in acute catarrhal bronchitis, chronic bronchitis of emphysema, bronchial asthma, purulent bronchitis, bronchiectasis, or the stasis-catarrh of cardiac disease.

should be patiently excluded, unless the associated evidences of commencing phthisis are conclusive. Phthisis in the stage of cavity may be confounded with *bronchiectasis* (*vide* Diseases of the Lungs).

Pseudo-tuberculosis.—By this term is meant a distinct form of pulmonary infection caused by the streptothrix *Eppingeri* or a closely related species, and clinically resembling pulmonary tuberculosis. Warthin and Olney¹ report 5 cases, and point out that the frequency of occurrence, the symptomatology, and the therapeutics of this form of streptothricosis remain to be worked out. The clinical picture presented is that of tuberculosis or bronchopneumonia. The diagnosis, however, demands isolation of an acid-resisting streptothrix. The tubercle bacillus is absent, but streptococci and staphylococci are found in association, and some of the cases may be of primary streptococcus infection.

FIBROID PHTHISIS.

Definition.—Fibroid phthisis implies induration followed by contraction of the affected lung-tissue, due to an increase in the connective-tissue elements. There are cases in which it cannot be distinguished pathologically from chronic pulmonary phthisis, but they differ clinically. The majority of instances are primarily tuberculous, though manifesting a strong tendency to the formation of fibrous tissue—a conservative process; in other instances the fibroid change may be primary, followed by tuberculous infection (*vide* Pneumonokoniosis). The usual form arises variously as a sequel of other morbid processes, such as—

- (1) Pneumonias, lobar (rarely) and catarrhal (commonly).
- (2) Pulmonary lesions—tubercle in the stage of consolidation or cavity.
- (3) Chronic tuberculous pleurisy.
- (4) Bronchial catarrh from inhalation of irritants (steel-, coal-, or mineral-dust).

Pathology.—The process in the beginning is very often localized in one apex, and less frequently in the middle portion of the lung or in the bases. It may remain circumscribed, but more often it extends downward, and gradually invades the entire lung. It is unilateral. Secondary to the induration and contraction there is dilatation of the bronchi.

The lung-tissue is hard and dense, the alveoli being obliterated. It resists cutting and creaks, and the section presents a smooth, dry, gray, often marbled aspect, though the fibrous tissue may undergo caseation.

The pleura is thickened, as a rule, often to a marked degree, and its layers are adherent; the unaffected portions of the lungs frequently become emphysematous. The right ventricle is, as a rule, hypertrophied.

Symptoms.—These may be briefly stated, since they do not differ from those of cirrhosis of the lung (*vide* Diseases of the Lungs). The onset is insidious: a persistent cough, occurring in severe paroxysms in the mornings, and a purulent expectoration are for long the leading features. If bronchiectasis is present, the sputum may be fetid. *Dyspnea* is marked, particularly on exertion. *Fever* is slight or absent, hence emaciation progresses slowly or may even be absent. The physical signs are identical with those of fibroid induration of the lung (*vide infra*).

The course of this disease is long, ranging from ten to twenty or even thirty years, and both lungs may become involved. Again, as in chronic

¹ "Pulmonary Streptothricosis," *Amer. Jour. Med. Sci.*, vol. cxxviii., No. 4, pp. 637-649.

pulmonary tuberculosis, prolonged suppuration may lead to amyloid changes in the liver, spleen, kidneys, and intestines. *Dropsy*, due to secondary dilatation of the right ventricle, often closes the scene.

Differential Diagnosis.—*Chronic bronchitis* may be mistaken for fibroid phthisis. In the latter disease, however, there are unilateral retraction and the signs of consolidation or of an apical cavity, and the sputum-test may settle the doubt.

Complications of Pulmonary Tuberculosis.—*Lobar pneumonia*, and less commonly *lobular pneumonia*, may develop and cause a fatal termination. In a study of 100 cases H. M. King found the principal complications of a non-tuberculous character were lobar pneumonia and nephritis.

Erysipelas may arise in the course of chronic pulmonary tuberculosis, though the proportion of cases is not formidable. Out of 1165 cases of erysipelas, 15 coexisted with pulmonary phthisis.¹ Some contend that its occurrence in this disease may be beneficial, but my own observations show that the gravity of both conditions is increased.

Typhoid fever may rarely be met with in sufferers from chronic phthisis. Out of a totality of 249 autopsies in cases of typhoid fever, only 19 (7.6 per cent.) showed the presence of tuberculous lesions.² This contradicts the opinion that typhoid fever predisposes to tuberculosis.

Chronic nephritis and pulmonary tuberculosis are often found in the same subject, and with these arterio-sclerosis is quite commonly combined.

Chronic endocarditis, particularly of the tricuspid segments, may also occur in phthisis, and from time to time cases of valvular heart-disease are reported, in which it is evident that passive congestion must have existed for some time before the tuberculous condition developed. The old doctrine of the mutual antagonism between disease of the left heart and pulmonary tuberculosis finds support from these cases, as in a large proportion a tendency to encapsulation of the tuberculous lesions exists.

Course and Duration.—Both as to course and duration this disease exhibits unusual variations. If not promptly treated during the incipient stage it frequently progresses with more or less rapidity toward the grave. It is common, however, to observe periods during which the disease is arrested or improved. Generally, the improvement, though followed by an exacerbation, endures for a long time, and permanent cures, even in the advanced stage, are by no means rare. The duration of pulmonary tuberculosis varies exceedingly, though from the collective investigations of different authors and from all the statistics available I find the average duration to be about three years. The late Austin Flint long ago directed attention to the innate tendency of a considerable percentage of the cases to spontaneous recovery—a fact that simply indicates a victory for nature's silent defensive processes in the struggle for supremacy.

In fatal cases death is by (a) *gradual asthenia* (most frequently), with retention of consciousness until the end approaches.

(b) *Complicating conditions* (bronchitis; pneumonia; pleurisy; pneumothorax; amyloid degeneration of the intestines, liver, spleen, kidney; Bright's disease; diabetes, etc.).

¹ "Points in the Etiology and Clinical History of Erysipelas," *Journal of the American Medical Association*, July 2, 1893.

² *Amer. Jour. of the Med. Sci.*, May, 1904, by the writer.

(c) *Tuberculosis of other organs*, particularly the meninges, intestines, and genito-urinary tract.

(d) *Hemorrhage*, due commonly to rupture of an aneurysm in the lung-cavity; less frequently to erosion of a large vessel. Fatal hemorrhage may, when the vomica is of large size, occur without hemoptysis, as in a case of Roland G. Curtin's at the Philadelphia Hospital.

(e) *Syncope*.—Though of comparatively rare occurrence, there are a number of events that may lead to sudden, fatal syncope—*e. g.* hemorrhagic embolism or thrombosis of the pulmonary artery, pneumothorax, thoracentesis for pleural effusion, walking about in a moribund state, etc.

(f) *Asphyxia* often closes the scene in acute pneumonic phthisis, and rarely in chronic phthisis complicated with pneumo-thorax, or with a large undiscovered or neglected empyema, or with sero-fibrinous pleurisy.

TUBERCULOSIS OF THE ALIMENTARY TRACT.

(1) **Lips**.—Whilst tuberculosis of the lip is quite rare, the possibility of its occurrence must not be forgotten. It assumes the form of a small ulcer, and the diagnosis is made by an examination of the labial mucus. It is usually associated with laryngeal or pulmonary tuberculosis. In *diagnosing* the condition, chancre and epithelioma must be excluded, the former by the history, and the latter chiefly by a microscopic examination for tubercle bacilli.

(2) **Tongue, Palate, and Tonsil**.—The work of Orth, Hanan, Schlenker, Kruckman, and others has shown that the tonsils, owing to their frequent inflammation, serve as the door of entrance of the tubercle bacilli. The fact that tuberculosis of the tonsils has repeatedly been found, and when other lesions of the disease were absent, points to the not infrequent occurrence of primary tuberculosis in this site. The infiltrated areas often present small grayish spots, but the appearance of the ulcers is not characteristic, frequently bearing a strong resemblance to epithelioma and to the syphilitic ulcer. The *diagnosis* demands either inoculative experiments or a microscopic examination of the oral mucus, the latter being oft repeated if necessary. E. D. Smith records 5 rare cases of tuberculous ulceration of the soft palate.

(3) **Pharynx and Esophagus**.—Both miliary tubercles and ulcerative lesions may rarely arise on the posterior wall of the pharynx by direct extension from laryngo-pulmonary tuberculosis or as the result of secondary inoculation. The chief symptoms occasioned are the excessive secretion of pharyngeal mucus and muco-pus, and painful deglutition. Tuberculosis of the esophagus is extremely rare.

(4) **The Stomach**.—Tuberculous lesions of the stomach are of exceptional occurrence. Marked gastric symptoms, however, are common, and they may be due to involvement of the larynx. I have been able to find reports of 4 cases of tuberculous gastric ulcer in addition to the 12 collected by Marfan.¹ The ulcers may be single (as in Musser's case) or multiple (as in Osler's case). The *symptoms* are not characteristic, but hematemesis occurring in patients suffering from tuberculosis of other organs should excite a strong suspicion of the existence of ulcer. Pain coming on soon after meal-time is more marked in tuberculous ulcer than

¹ *Paris Thesis*, 1887.

in ordinary gastric lesions. Perforation may take place. Four cases are recorded in which the pylorus was found encircled with a flat, granular ulceration, operated on under the diagnosis of carcinoma (Alexander¹). The process was isolated and the symptoms all pointed to pyloric cancer.

(5) **Intestines.**—The lesions may be (a) primary or (b) secondary.

(a) Primary tubercle of the intestines is chiefly met with in children, for the reason that they are more likely to swallow the tubercle bacilli with their food, and especially in milk. The intestinal route of infection is, according to my own observation, more common in adults also than is supposed. Many cases during life present the features of both intestinal and peritoneal tuberculosis, and it is often impossible to determine which of these was the primary condition; and the same difficulty arises when the cases come to autopsy. I have never seen an instance (post-mortem) of intestinal tuberculosis in which the peritoneum and mesenteric glands were not involved to an equal degree.

(b) The secondary variety occurs in more than one-half of the cases of pulmonary tuberculosis, the chief seats of the lesions being the lower part of the ileum, the cecum, and the upper part of the colon. The rectum is also the seat of secondary tuberculosis in a small proportion of the cases of chronic phthisis and it may be rarely a primary seat of the affection.

The morbid process begins in the solitary glands in Peyer's patches, where at first grayish, firm tubercles grow and form little prominences. These caseate, becoming yellow in appearance, and then soften and disintegrate, producing ulcers. Osler thus describes the characteristics of the tuberculous ulcer: "(a) It is irregular, rarely ovoid or in the long axis, more frequently girdling the bowel; (b) the edges and base are infiltrated, often caseous; (c) the submucosa and muscularis are usually involved; and (d) on the serosa may be seen colonies of young tubercles or a well-marked tuberculous lymphangitis." In all *acute* cases the surface-lesions show little tendency to repair (Senn).

In *chronic* cases attempts at healing are the rule; and the cicatrices are extensive and often pigmented, and as they undergo contraction may produce incomplete or even complete stricture of the bowel. At a point corresponding to the seat of the ulcers local peritonitis invariably develops. The serosa is thickened and adherent, and the ulcer may penetrate through this coat without causing perforative peritonitis, while rarely a fistulous connection is established between the different parts of the intestine.

Symptoms.—In children the symptoms are those of a protracted catarrh of the intestines, or they may be absent. Among prominent features are diarrhea, colicky pains, and the presence in the stools of pus, blood, and particles of mucus resembling sago-grains. In many cases there is constipation, which may be due either to peritonitis or cicatricial stenosis. The general symptoms are irregular fever, wasting, and a lack of development; they are especially valuable for diagnosis.

In adults intestinal tuberculosis generally gives rise to symptoms similar to the above, and when they arise in the course of pulmonary phthisis they are highly significant. If diarrhea be present, it stubbornly resists treatment, and it must not be forgotten that it may also

¹ *Deutsches Archiv f. klinische Med.*, Berlin, lxxxvi., Nos. 1-3, 1906.

be due either to catarrhal colitis or to amyloid change, both of which processes may be associated with chronic phthisis. Constipation is common and often marked, and local tenderness and colicky pains are complained of frequently. The pulmonary signs, however, may be in abeyance.

If the abdominal and general symptoms are such as to excite suspicion of this disease, then a rigid physical examination of the lungs should be made. The chief seat of the lesions may be for a long time in the cecum, or in the appendix, when the symptoms—both local and general—will be those of appendicitis.

The *diagnosis* of primary intestinal tuberculosis is beset with special difficulties. Sawyer¹ has in special instances demonstrated the presence of clusters of tubercle bacilli in the rectal mucus, and in this way the recognition of intestinal tuberculosis at an early date, or before diarrhea sets in, is rendered possible. The mucus is obtained after placing the patient in a position as if to examine for piles, and directing him to bear down as though at stool, by gently removing a small quantity from the everted membrane with a sterile loop. It is then spread upon a clean cover-glass and treated exactly as sputum in the ordinary examination. The same method is applicable to cases of secondary intestinal tuberculosis, but here the history and associated tuberculous lesions usually serve to remove all doubt.

TUBERCULOSIS OF THE SEROUS MEMBRANES.

General tuberculosis of the serous membranes *secondary* to pulmonary and intestinal tuberculosis is of common occurrence, and that a *primary* form of tuberculosis of the serous membranes also occurs is undoubted. Unfortunately, accurate means of discriminating the secondary from the primary form are wanting, since often in the secondary variety the primary lesions in other organs are insignificant.

The anatomic alterations resemble those of ordinary inflammation of these structures, plus the presence of nodular tubercles. The latter may be observed, as a rule, only over small, scattered, circumscribed areas, though not infrequently they are both numerous and diffuse (general miliary deposit). The effusion is in most instances sero-fibrinous, though sometimes it becomes purulent, and not uncommonly it is hemorrhagic. Most instances of so-called hemorrhagic pleurisy are due to pleural tuberculosis.

Clinically, cases are divisible into (1) acute serous membranous tuberculosis and (2) the chronic form. The *acute* form results from inoculation of the peritoneum or pleura, induced by limited foci in the bronchial, tracheal, or mediastinal lymph-glands, or in the Fallopian tubes in women. The *chronic* type is apt to result from a direct extension of a tuberculous process from some organ adjacent to the pleura or peritoneum, though it may attack the serous membranes primarily. Belonging to this class of diseases are two groups of cases: those attended by sero-fibrinous or sero-purulent effusion and the presence of caseous masses, and those in which there is a tuberculous deposit with increased density and great

¹ *Medical News*, May 23, 1896.

thickening of the pleural layers, and slight exudation. The pericardium may be similarly involved.

(a) **Tuberculous meningitis** has been described fully in the present section (*vide* Miliary Tuberculosis).

(b) **Tuberculous Pleuritis**.—This subject will be referred to in the section on Diseases of the Pleura. Its import, however, is such that brief special consideration is demanded, and from a clinical view-point the cases may be grouped under two heads—namely, *acute* and *chronic tuberculous pleurisy*.

The *acute* form often has a sudden onset, the initial symptoms being a rigor or repeated fits of chilliness, a stitch-like pain in the side affected, shallow, catching breathing, a cough, and fever. The ushering-in symptoms sometimes suggest lobar pneumonia, and a fatal termination is not uncommon, though apparent recovery or a transition into chronic tuberculous pleuritis also occurs.

Chronic tubercular pleurisy is vastly more common than the acute form, and it is sometimes primary, though more often secondary to pulmonary tuberculosis. In all cases of the latter disease in which the periphery of the lung becomes involved the visceral layer of the pleura is invaded. This leads to plastic pleurisy with adhesion, and the membranes contain disseminated tubercles, or to sero-fibrinous tuberculous pleurisy. As above stated, the effusion may be hemorrhagic and may also become purulent. When the tuberculous pulmonary focus perforates the pleural sac, pyopneumothorax is produced. In tuberculous pleurisy, as opposed to simple pleurisy, there is usually an absence of leukocytosis.

Symptoms.—The *onset* is very insidious and often unnoticed. There may be few symptoms, and yet a physical examination reveal a large sero-fibrinous exudate. The cough and other symptoms are frequently due to a coexisting tuberculosis of the lungs, and the presence of subcrepitant and dry râles is strongly confirmatory of tuberculous pleurisy. By and by the evidences of pulmonary tuberculosis are of diagnostic importance, or the supervention of acute general miliary tuberculosis makes clear the nature of the case. The *subacute variety* with effusion may terminate, after absorption of the exudate, in chronic adhesive pleurisy with great thickening of the membrane. The latter may also originate as a primary proliferative process.

(c) TUBERCULOSIS OF THE PERICARDIUM.

The morbid lesions are analogous to those of tuberculosis of the pleura. The effusion may be enormous on the one hand or insignificant on the other, and it is often hemorrhagic, while in the chronic form there is marked thickening of the membrane with the deposit of tubercles and cheesy masses. The affection is less common than tuberculosis of the pleura, yet not so rare as was formerly supposed, and occurs in the acute and chronic forms.

Acute tuberculous pericarditis is rarely a primary affection, and, as a rule, originates secondarily to pulmonary, pleural, or glandular tuberculosis. It is especially prone to arise in tuberculosis of the bronchial and mediastinal lymph-glands, and, as the latter condition is frequent in young children, so tuberculosis of the pericardium is relatively frequent at this period, though it may occur at any time of life. Pericardial

tuberculosis also results from direct extension from a contiguous focus. The symptoms will be detailed in the discussion of Pericarditis. In the *diagnosis* of the affection the history and any associated tuberculous processes detectable must be taken into account, and a point of some diagnostic value rests in the fact that tuberculous pericarditis does not show the usual inflammatory leukocytosis.

Chronic Tuberculous Pericarditis.—This may be a part of the general tuberculosis of the serous membranes, or it may follow an infection of the bronchial and mediastinal glands (most frequently), lungs, pleura, or peritoneum. Cases of primary origin also occur, but they are exceedingly rare, the neighboring lymph-glands being generally involved. This form is also dependent upon direct extension from the spine and sternum.

From personal observation I am convinced that the cases naturally fall under two heads, when considered clinically: those without effusion, in which the pericardium is adherent; and those with more or less effusion. The former are the more frequent, though often entirely latent, the adherent pericardium leading to hypertrophy of the heart, followed sooner or later by dilatation. The signs are therefore those of adherent pericardium, with the occasional difference that the dulness may extend higher up over the sternum, in consequence of the presence of firm, cheesy masses at the base of the heart and also encircling the aorta. The smaller group of cases (in which the effusion is present) resembles dilatation of the heart in its clinical manifestations. I recall one instance of this sort that occurred in a male aged about sixty years at the Episcopal Hospital, the autopsy revealing extensive pulmonary tuberculosis and chronic tuberculous pericarditis, with the presence of eight ounces of hemorrhagic effusion.

(d) TUBERCULOSIS OF THE PERITONEUM.

This is dependent upon infection by means of the bacilli circulating with the blood, or upon extension of tuberculous inflammation or ulceration from adjacent organs. In 11 per cent. of 3405 autopsy records Cummins¹ found there was peritoneal involvement. Mention has already been made of the fact that the intestines are often invaded by tuberculosis, and that the serosa is quickly involved in such instances. The condition may rarely be primary. This involvement may remain circumscribed and undergo spontaneous cure if the intestinal lesion cicatrizes, as post-mortem findings frequently indicate, but in extensive peritoneal involvement spontaneous resolution is out of the question. These cases may be subdivided into acute and chronic. The *very acute cases* are those forming a part of acute general miliary tuberculosis, or due to perforation into the peritoneal sac from adjacent organs, and Adlebert's classification is as follows: (a) The ascitic form, (b) the ulcerous form, and (c) the fibroid form. Though these groups do not present sharp clinical distinctions, the courses they run vary considerably, as do the results of treatment. In the *ascitic* form the exudate is purulent or sero-purulent, and is often encapsulated. In the *ulcerous* the tuberculous new-formations, which may be quite large, undergo caseation and ulceration, the latter process being progressive, so that it may perforate the walls of the intestines. This and the ascitic variety may be combined.

¹ *University Med. Bulletin*, December, 1905.

In the third or *fibroid* form the peritoneal surfaces are adherent. There is little exudation; the tubercles may be numerous and diffuse, or found only in scattered localized areas. The lesions may represent the concluding stage of acute or subacute tuberculous peritonitis.

Etiology.—Most cases are produced by extension of tuberculous inflammation from adjacent organs, and of 107 cases analyzed by Phillips the lungs were involved in 99, the pleura also in 60, and the bowel in 80. Children are frequent victims to intestinal tuberculosis, and the bacilli often reach the peritoneum through the intestines, as they are also apt to do in adults suffering from chronic phthisis. Extension from the pleura to the peritoneum is frequent (pleuroperitoneal), but from the pericardium is rare. In females the starting-point is often the Fallopian tubes (Mayo, Murphy), and in either sex it may be the appendix.

Predisposing Factors.—**Age.**—During the period from fifteen to forty years the incidence is most frequent, although it is not uncommon in children under ten years, nor between the fortieth and fiftieth years of life. Subsequently, it rapidly decreases in frequency. I agree with Osler in stating that in America negroes are more prone than whites.

Sex has a tolerably potent disposing influence. Abdominal surgeons have taught us that the disease occurs more frequently in females than males, owing to the fact that the Fallopian tubes are a favorite seat for primary tuberculous infection. The ratio based upon sex is as 3 to 2 in favor of females.

Symptoms.—Some cases develop *abruptly* with *severe symptoms*, as fever, marked constitutional disturbance, rapid small pulse, abdominal *pain*, *vomiting*, and sometimes *diarrhea*. The *temperature* may be quite high (103° to 104° F.—40° C.), or it may be only slightly elevated even in the worst cases. There follow quickly such symptoms as *anemia*, *marked emaciation*, and a pronounced *typhoid condition*. The signs of *peritoneal effusion* (rarely large) are soon in evidence, and are attended sometimes by a suppurative type of temperature, sweats, etc., indicating the presence of *pus* in the peritoneal sac. A few cases are unattended by ascites, and here nodular masses are palpable, while on auscultation friction-sounds may be audible in the umbilical region. *Tympanites* due to intestinal paresis, is common in cases having an acute onset.

The *acute stage* may be absent, the affection then being marked by slight local and general symptoms (low fever, anemia, slight belly-pains, and a sense of distention). The skin is sometimes pigmented, and usually in patches. There are not a few instances in which the affection is latent, and in one case of this sort with ill-defined general symptoms pigmentation of the skin first directed my attention to the peritoneum.

The **physical signs** of moderate ascites frequently, and those of enlarged mesenteric glands sometimes, are present. These conditions are often combined in children, constituting the so-called *tabes mesenterica*. I cannot conceive of the occurrence of this association of symptoms without simultaneous involvement of the peritoneum, and doubtless co-involvement of the latter membrane and intestines usually occurs. Hamman emphasizes the great frequency with which more than one serous membrane is affected (multiple serosites). The tuberculous new growth in the peritoneum may also form a distinct tumor not unlike that produced by glandular enlargement, while the intestinal coils

with their now thickened walls are sometimes knotted together so firmly as to simulate a dense new growth. The exudation may be loculated owing to adhesions between peritoneal layers of the intestinal coils, etc., producing a localized tumor varying in size and position. Such sacculated exudations most frequently occupy the pelvic or umbilical regions, though they may also be found elsewhere in the abdomen. They may be multiple, and are not infrequently too small to be recognized by the physical signs, being often discovered during laparotomy. On the other hand, they may occupy a large portion of the abdomen. An *omental* tumor of characteristic elongated form (produced by a shrinking and curling up of this membrane) is demonstrable, its long axis generally taking a transverse direction just above the umbilicus. Gardiner has observed this tumor to disappear by spontaneous resolution in children.

The dry, fibrous variety, which is not infrequent, is often latent, and the condition may be general or localized. It is decidedly more frequent in adults than in children. The *symptoms* are far from characteristic. Among local features are pains, abdominal distention (giving rise to a tympanitic note on percussion), tenderness on pressure, and sometimes a tumor-ridge extending across the upper abdominal region. Among general symptoms are usually anemia and emaciation, with or without fever. Indeed, the temperature may be subnormal, and these cases may show a tendency to spontaneous recovery.

Diagnosis.—Unless tuberculosis of other organs can be demonstrated the diagnosis is often impossible. This is particularly true in cases in which there is no abdominal pain, which is the most important local symptom, nor tenderness. Fever and the presence of a tumor, especially if the latter be elongated and lies transversely in the umbilical region, are important aids; but if tuberculosis of the lungs, pleura, pericardium, appendix, and the tubes, in women, can be excluded, the rectal mucus and the urine should be examined for tubercle bacilli. From the *acute form* several affections must be discriminated:

(a) *Internal Hernia*.—This comes on suddenly; the pain is strictly localized and paroxysmal; stercoraceous vomiting appears in a few hours; the constipation is absolute, and tympanites is marked, but ascites is absent.

(b) Similar symptoms belong to *volvulus* and to the quick incarceration of loops of intestine under bands of adhesions; on comparison they will be seen to differ from those of acute tuberculous peritonitis.

(c) *Enteritis* is discriminated from *acute tuberculous peritonitis* by the presence of copious mucous discharges, and by the absence of associated tuberculous lesions, ascites, tumors, and the phenomena of the typhoid state.

Chronic tuberculous peritonitis often closely simulates *cancerous peritonitis*, owing to the fact that the elongated omental tumor may be met with in both, associated with ascites, abdominal pain, and slight fever. In carcinoma, however, there is an absence of the tuberculous history and lesions, and the presence, sometimes, of a gradually increasing tumor of primary growth, the slowly oncoming intestinal obstruction from pressure, and the cancerous cachexia. Moreover, tuberculous peritonitis occurs more commonly in younger subjects, and is more apt to be interrupted by periods of improvement, followed in turn by rather alarming symptoms. The tuberculin test is to be used in dubious cases.

Locular exudations must be distinguished from *ovarian tumors*, and here the history, together with tuberculous lesions elsewhere in the body, the occurrence of febrile attacks, and intestinal disturbance with pain, are of great diagnostic significance. Such cases should be examined by a gynecologist, since, however expert the examiner, when the saccular exudations are located in the pelvic region an exploratory laparotomy must often decide the nature of the condition. Finally, it must not be forgotten that the vast majority of cases of chronic peritonitis are tuberculous.

TUBERCULOSIS OF THE LIVER.

The liver was formerly overlooked in many instances of tuberculosis, because the lesions, particularly in acute tuberculosis, are often microscopic. In the chronic disseminated variety, however, grosser changes are observed, the organ being slightly enlarged, pale, and fatty, and presenting an irregular surface like that of an orange. On section, the parenchyma cuts with great resistance, being very dense (tuberculous cirrhosis). Minute gray and larger yellow masses are seen, especially just under the capsule, and small cavities, the result of a breaking down of the cheesy masses and containing pus and bile, are also observed. These changes are most pronounced about the bile-ducts.

Etiology.—The liver is implicated in all instances of acute miliary tuberculosis. It is also involved secondarily in chronic tuberculosis of the lungs, pleura, peritoneum, spleen, lymphatics, etc.

Symptoms.—This is a common condition, the organ being appreciably enlarged and its surface presenting irregular, palpable prominences. The clinical features of *perihepatitis* and *peritonitis* are often found in combination. Ascites may be present, but is rare.

TUBERCULOSIS OF THE GENITO-URINARY SYSTEM.

(1) **Tuberculosis of the Kidneys.**—This may be primary or secondary, the secondary form being the more common, and it may be either unilateral or bilateral.

Pathology.—The process begins in the calices and apices of the pyramids (papillæ), thence proceeding to the pelvis of the kidney, so that early the condition may be pyonephrosis. The morbid changes then extend to the ureters, and sometimes to the bladder and prostate, and instances are even met with in which the process seems to have crept from below upward, starting from the bladder or prostate. The tubercles pass through the usual stages of caseation, necrosis, and suppuration, and destruction of the renal tissue to a greater or lesser degree occurs, with the formation of cysts containing cheesy material in which lime-salts may be deposited. When the process invades the kidneys through the blood, it may be limited largely to the cortical layer and give rise to nodular tuberculosis with caseous masses, yet with little loss of renal substance. H. A. Kelly¹ believes that the infection of the kidney is almost always hematogenous. While it is difficult to judge of the relative ages of the lesions in different organs, I cannot escape the conviction that in a

¹ *British Medical Journal*, June 17, 1905, p. 1319.

small group of cases renal tuberculosis is an *ascending* process and follows ureterocystic tuberculosis. Although both kidneys are finally involved in most instances, for a considerable period the disease is unilateral. Hallé and Motz found one kidney alone affected in 89 out of 132 cases.

Etiology.—Of disposing factors *age* and *sex* deserve especial mention, most cases occurring during middle life, though they are by no means rare both at an earlier and a later period. The disease is more frequent in males than females.

The bacilli reach the kidneys with the blood-stream, producing primary renal tuberculosis, through the lymphatics and direct extension from adjacent structures.

Symptoms.—In many cases there are either no renal symptoms or none until a late stage is reached, but the symptoms of pyelitis are usually present. *Pyuria* may be the only symptom for a long time, and this symptom, according to certain authorities, points directly to cystitis. When the latter condition is present, however, the micturition becomes frequent and there is vesical tenesmus. *Pain* in the side chiefly affected is complained of, and is sometimes not unlike renal colic; hematuria is not rare, and it may be the initial symptom, and a cystoscopic examination may show the blood to be of renal origin (Tuffier). It is useful also in showing the state of the bladder-mucosa. The demonstration of tubercle bacilli in the urine, especially if arranged in S-shaped groups, is diagnostic (Frisch). When the bacilli cannot be found, inoculation-experiments upon guinea-pigs and rabbits furnish an accurate criterion, though it must not be forgotten that tubercle bacilli may find their way into the urine from more distant tuberculous foci. Catheterization of the ureters may determine which kidney is involved. *Polyuria* is sometimes present, as well as *albuminuria*; the urine may also show *tube-casts* (rarely) and pus-cells. Macroscopic cheesy masses are occasionally found.

The *general features* are often marked, but not until the affection becomes advanced, chills, fever of a suppurative type, emaciation, and increasing debility being the principal symptoms. Associated tuberculous lesions, especially of the lungs, are constantly observed.

Physical Signs.—Inspection may show a tumor-like prominence on the side chiefly affected, though rarely of large size. Palpation often detects tenderness, and the outline of the organ may be defined by careful firm pressure with the finger-tips.

Diagnosis.—It is difficult to discriminate *calculous pyelitis*. In the latter, however, the pain is severer, the tumor-mass larger, and the hemorrhage more frequent than in tuberculous nephritis. The discovery of tubercle bacilli or the demonstration of tuberculosis of the lungs or other organs would remove all doubt. The tuberculin test may be used.

(2) **Tuberculosis of the Ureter and Bladder.**—This is almost always secondary to tuberculous disease of the pelvis of the kidney above, or of the deep urethra, testes, or prostate below. When primary, as rarely happens, the bladder is in most instances invaded last. The *symptoms* are those of chronic cystitis, and in all cases in which no other cause for the latter can be found the primary tuberculous lesion must be sought for and the urine carefully examined for bacilli. The smegma bacillus,

sometimes present in normal urine, can be distinguished by decolorizing with absolute alcohol, which will take place in about two minutes, while with the tubercle bacillus a very much longer time is required. Others say this is not sufficient, and that only their methods of culture-growth or inoculation will distinguish them. A catheter specimen should be obtained if possible (Ogden). With the development of ulcerative lesions hemorrhage is apt to arise.

(3) **Tuberculosis of the Vesiculæ Seminales, Prostate, and Testes.**—The prostate gland and testes are frequently invaded in genito-urinary tuberculosis, and the vesiculæ seminales somewhat less frequently. The morbid process leads to the formation of cheesy nodules, which may, though comparatively rarely, disintegrate, causing excavations or perforation. Rarely, the tubercle does not pass through the stage of caseation, but merely shows the presence of numerous embryonic cells.

Etiology.—The condition is usually secondary, but the existence of primary tuberculosis in these organs cannot be denied. Testicular tuberculosis may begin at any period of life, and is of rather frequent occurrence in infants. When it occurs in the latter, it is part of a more general tuberculous infection, and is in many instances undoubtedly congenital. In some cases it may be a late hereditary affection.

Symptoms.—In the *testicle*, tuberculosis, as a rule, induces a painless, protracted orchitis, though when cavernous lesions occur the symptoms are more acute. In *prostatic tuberculosis* the bladder is highly irritable, there is great distress felt in the thigh and groin, and micturition is very painful. Catheterization, particularly if the urethra (as is very rarely the case) is the seat of tuberculous ulceration, causes most excruciating suffering, and there may be signs of stricture. *Rectal palpation* detects in the prostate firm nodules varying in size from a pea to a bean, together with enlargement of the organ.

Diagnosis.—The diagnosis of tuberculosis of the prostate is easily made from the vesical symptoms, the presence of tuberculosis in other organs, the result of rectal examination, and the detection of bacilli in the urine. Syphilitic involvement of the testicle is sometimes excluded with difficulty; in the latter disease, however, the surface of the swollen organ presents greater irregularities, and is even less painful than in tuberculosis. The absence of the history of syphilitic infection and the presence of tuberculosis in other organs, particularly in the uro-genital system, are valuable points in the discrimination.

TUBERCULOSIS OF THE FALLOPIAN TUBES, OVARIES, AND UTERUS.

Tuberculosis of the tubes in women is a not infrequent condition, and may be primary.

Etiology and Pathology.—The tubes, as a result of infiltration, are thick, hard, and bound down by false membrane. Their ends are generally closed, but the intervening portion is dilated, and contains mucus, pus, and cheesy material. A catarrhal salpingitis is generally in association. *Uterine tuberculosis* is rare, and its origin is usually attributable to similar involvement of the tubes.

The disease is most common during the period of greatest sexual

activity, but young children may suffer (*vide* literature of Hennig), and in them the ovaries and uterus may be implicated without participation of the tubes, as in cases reported by Gusserow. At any period of life the lesions may be microscopic; they usually, however, excite marked local peritonitis, which may become general, with the development of ascites. The process may extend to the vagina.

Diagnosis.—The age, family history, and signs of the tuberculous diathesis must be noted. The disease does not distinguish itself from other tubal tumors by anything characteristic on bimanual palpation. Cases occur with ascites and also without, and in the latter variety plaque-like thickening of the subperitoneal tissue is an aid to diagnosis. The uterine secretions should be examined for bacilli in all obscure cases. Ashton advises an exploratory incision or puncture and examination of the contents of the peritoneum or tubes for bacilli.

TUBERCULOSIS OF THE MAMMARY GLANDS.

This is rare; the affected glands present fistulæ and ulcers, with induration of the organ and retraction of the nipple. Warden¹ reports the finding of 58 authentic cases in the literature. Nearly 90 per cent. of the patients were females, and most cases developed in the third decennium. The *symptoms* are sharp and lancinating pains radiating to the arm, and tumor, the latter consisting of one or more nodules. Pyogenic secondary infection, leading to obstinate fistulæ, is common. The axillary glands are often enlarged. A positive *diagnosis* rests crucially upon the finding of the bacilli in the pathologic secretions.

TUBERCULOSIS OF THE BRAIN.

Pathology.—Tuberculosis of the brain occurs in two forms, one of which, acute tubercular meningitis, has been previously described, while the other is a chronic tuberculous infection, usually localized, of the meninges and cortex, and causing meningo-encephalitis. Very rarely the membranes remain intact. The so-called solitary tubercle is an irregularly round mass, varying in size from a small pea to an apple or even larger. It is generally single, though sometimes there are two, and rarely even three, nodules. The tubercle may be imbedded in, and be contiguous with, the brain-substance, or may be separated from the latter by cysts. The peripheral zone is formed largely of connective tissue, is lighter in color (often translucent), and may contain miliary tubercles, while the central portion, which is cheesy as a rule, may liquefy and thus form a small cavity containing a purulent-looking material. They are seen with greatest frequency in the inferior portions of the brain.

The new growths may compress the longitudinal sinus, inducing thrombosis; they may interfere markedly with the circulation, causing cerebral softening; and, finally, they may excite acute tuberculous meningitis. Tuberculosis of other organs is usually found as an associated condition.

Etiology.—The disease occurs with especial frequency in young subjects, and, according to the statistics of Pribram, in about three-

¹ *Medical Record*, October 1, 1898.

fourths of the cases before the fifteenth year. The symptom-picture is identical with that of brain-tumor (*q. v.*).

TUBERCULOSIS OF THE SPINAL CORD.

The lesions are those of solitary tubercle of the brain. It is an extremely rare condition, and almost invariably secondary. (For symptoms, *vide* Spinal Tumor and Meningitis.)

TUBERCULOSIS OF THE HEART.

(a) *The Myocardium.*—Tuberculous myocarditis, though comparatively rare, is more common than has been supposed. It may be primary, although practically always secondary to a focus in some other tissue, and transmission to the heart generally occurs by way of the lymphatic system. Infection through the agency of the pericardium is also common, and rarely it may be by the blood. Three *pathologic* varieties (here mentioned in the order of relative frequency) are recognized: (a) Large tubercles; (b) Miliary variety; and (c) Diffuse form, or tubercular infiltration. Generally speaking, the smaller nodules are found usually in the ventricles, and the larger masses in the auricles, chiefly the right. In miliary tuberculosis scattered gray granulations or semitransparent areas are formed. The literature furnishes a total of 72 cases, nearly one-half of which have occurred in persons under fifteen years of age, and is quite rare after the forty-fifth year. The *diagnosis* is exceedingly difficult, and rarely possible. In addition to the suspicious features, such as syncopal attacks of short duration or sudden collapse, with comparative well-being in the intervals, that may be present, the existence of generalized tuberculosis and pericardial tuberculosis, one or both, are essential to a diagnosis. Death may occur suddenly.¹

(b) *The Endocardium.*—True tuberculous endocarditis is a rare condition. It is most apt to occur in acute miliary tuberculosis. The endocardium is to an unusual degree resistant to the tubercle bacillus. In tubercular invasion of the mediastinal glands the endocardium may become involved by extension of the morbid process. Infection of the endocardium also takes place through the blood supply to the heart structure. Vegetations occur on the valves, and in cases in which the lesions are of the ulcerative variety secondary pyogenic infection probably exists. Clinically, the cases of tuberculous endocarditis are extremely difficult of recognition. The history of the case, however, may be of diagnostic significance. "If it can be shown that the cardiac affection developed subsequent to undoubted pulmonary tuberculosis, and if rheumatic and other forms of infectious endocarditis can be eliminated, and especially if there have been neither previous arteriosclerosis nor fibroid degeneration of the viscera, then a reasonably certain diagnosis of tuberculous endocarditis, given the usual signs and symptoms, can be made."²

¹ "Tuberculous Myocarditis," *Journal of the American Medical Association*, Nov. 1, 1902, by the writer.

² *American Journal of Medical Sciences*, January, 1902, by the writer.

TUBERCULOSIS OF THE ARTERIES AND VEINS.

This may arise from extension of an adjacent tuberculous process into the vessel, as in chronic phthisis. It causes infiltration of the arterial wall, resulting in thrombosis, or the vascular tubercles may caseate and soften, thus leading to hemorrhage. In tuberculous meningitis the arterial lesions are conspicuous. The perforation of a vein by an old focus is followed by a distribution to all parts of the body of numerous bacilli and the production of acute miliary tuberculosis. Infection of the arteries may also occur through the blood. Of 1778 cases of pulmonary tuberculosis, thrombosis occurred 19 times, most commonly in the veins of the lower extremities (H. Ruhl and Hierokles).

General Prognosis.—The prognosis is best reached as in other infectious diseases—namely, by taking into account (*a*) the severity of the type of the disease; (*b*) the presence or absence of frequently associated diseases or complications; and (*c*) the numerous circumstances connected with individual patients.

(*a*) **The Severity of the Disease.**—Though there are no accurate criteria, we may judge of the severity of the disease by its progress, by the result of proper treatment, and from certain symptoms. If the fever be high, the prostration marked, and the local lesions rapidly advancing, we may safely infer that the disease is of aggravated type. With these certain other considerations are closely connected—the stage of the affection and the extent of the local lesions. Thus at an early stage the prognosis is more hopeful than at a late period, and, similarly, when the lesions are strictly localized at one apex it is more hopeful than when they have reached the stage of extensive cavity-formation or are bilateral. As already stated, a certain proportion of the cases manifest an inherent tendency to spontaneous arrest or even cure, and this may occur even after the stage of excavation has supervened. Notwithstanding this truth, however, it is well to make in all undoubted instances of the disease a guarded prognosis. A common error is the mistaking of a temporary for a permanent arrest of the tuberculous process, and in the natural history of the affection the fact was emphasized that its course was interrupted by periods of comparative comfort and noticeable improvement, followed by sharp exacerbations.

(*b*) **Associated Diseases and Complications.**—These unfavorably modify the prognosis—marked toxic symptoms (*e. g.*, rapid pulse, high temperature, rapid emaciation), chronic nephritis, gastric complications, intestinal and laryngeal involvement. Some of the accidents of the disease may precipitate a fatal result (*vide* Modes of Death). The appearance of intercurrent acute pneumonia is indicative of danger. The detection of secondary infective agents in the sputum renders the outlook worse. Other complications have been detailed in the Clinical History.

(*c*) **Circumstances Connected with Individual Patients.**—(1) A feeble, delicate constitution, either acquired or inherent (tuberculous diathesis), increases the morbidity of tuberculosis.

(2) When the fever subsides and the patient gains flesh and strength, the outlook at once brightens. Konzelmann has observed a number of instances in which a tuberculous process of the lungs healed under the influence of a pleural effusion, the theory being that the affected lung is given rest. The temperature and local symptoms often promptly subside.

(3) *Hygienic Surroundings*.—When the hygienic regimen under which the patient lives is the best, the prospect is more hopeful than when it is faulty. A proper diet aids favorable progress, while a defective one often turns the scales against recovery. Equally influential for good is a pure atmosphere, while, *per contra*, a vitiated one is injurious.

(4) *Age*.—In young subjects from five to fifteen years of age tuberculosis often pursues an acute course and the mortality-rate is exceedingly high. Chronic tuberculosis may, however, form a sequel, and under appropriate surroundings may lead to recovery. In chronic phthisis "the younger the patient the shorter the duration." I have observed that patients who give a history of pleurisy early in life do not bear chronic phthisis well. Naegeli¹ found, as the result of 500 autopsies at Munich, that in persons over thirty years of age every one had been more or less successfully attacked by the bacillus tuberculosis; but from the fact that most deaths had occurred in subjects under thirty, he concludes that the adult body is, as a rule, well able to resist the attack. "The absence of a tuberculous family history has but slight, if any, favorable significance" (Bonney). During old age pulmonary tuberculosis is usually more or less latent, and, owing to coexistent emphysema and chronic bronchitis, pursues a slow course.²

(5) The gravity of tuberculosis may be determined with some degree of accuracy by the use of creasote in gradually ascending doses. Hence this agent has a prognostic value.

(6) Römer and Joseph³ claim to have demonstrated beyond question that one infection with the tubercle bacillus confers a certain protection against subsequent infection.

TREATMENT OF TUBERCULOSIS.

Prophylaxis.—(1) This embraces thorough and prompt disinfection of the sputum as the best preventive element. To this end the patient must be taught to expectorate at all times into a spittoon or spit-cup which

FIG. 25.—Pasteboard spit-cup for receiving infectious sputum. When used the pasteboard can be removed from the steel frame and burned.

contains a proper disinfectant solution, and when the breaking-down stage has arrived portable flasks (*e. g.* Dettwiler's) containing an antiseptic solution must be worn by the patient, even while out of doors. Afterward the sputum is to be destroyed by boiling or burning and the spit-cup sterilized. The sweat of tuberculous patients should be removed at intervals, and the surface of the body bathed with appropriate antiseptics.

(2) **Isolation.**—After the stage of softening is reached the patient

¹ *Hyg. Rundsch.*, 2, 1901.

² A physician should not neglect to examine the sputum in suspicious cases for bacilli.

³ *Beiträge zur Klinik der Tuberkulose*, Wurzburger, xvii., No. 3, p. 281.

should invariably occupy a separate apartment, since, despite great care, the room and bed occupied by the consumptive become in time a source of infection. Hence, unwashable hangings and upholstered furniture, as well as other objects that facilitate the harboring of the bacilli, should be removed from the sick-room. The floor of the apartment should not be carpeted, but may in part be covered with rugs that can be frequently taken up and shaken in the open air. For like reasons, special hospitals and sanatoria for the treatment of the tuberculous poor are a necessity. Flügge's important researches (*vide supra*) show that phthisical patients should wear a mask day and night, that should be removed only for eating and to expectorate. Tuberculous patients in the infectious stage of the disease should be retired from occupations in which they may infect others (Flick). Kissing by the patient must be prohibited and all things used or worn by him should be kept apart from those used by the family or his friends. The prevention of auto-infection, which often results from the swallowing of sputum, is most important.

(3) **Compulsory registration** of tuberculous (pulmonary) patients is desirable. This insures thorough disinfection by health officers of houses in which deaths from phthisis have occurred, and serves to cut off many of the varied channels of transmission of the tubercle bacillus, provided that the measures applied be not rigorous.

(4) **Government Inspection of Dairies and Slaughter-houses.**—This is the serious business of the State, and, since infection through food, especially milk, is quite common in infants, skilled veterinary inspection of dairies is of prime importance. Of the greatest benefit would be the killing of all tuberculous cattle, and of less though decided efficacy the confiscation at the abattoirs of all carcasses that present marked lesions.

(5) **The popularizing of information** relating to the dangers of, and the means of stamping out, this great scourge. This may be in part accomplished by mural placards, stating simple, plain facts about the way in which the disease is spreading. Armaingaud suggests the placing in the homes of the people printed matter in a form suitable for preservation.

(6) **The Removal of Known Predisposition to the Disease.**—The tuberculous diathesis, whether inherited or acquired, must be overcome, if at all, by vigorous measures or by better hygienic living. In attempting to remove the phthisical tendency the physician must place chief reliance upon the most favorable environment attainable. The value of a change of residence—from the city to the country, the seaside, or the mountains, in selected cases—cannot be overestimated. It often renders predisposed persons immune. For some, and particularly young subjects, an equable climate (Southern California or Florida), that will enable them to live an out-door life is to be preferred. Attention to the food must not be forgotten. Milk and raw eggs are excellent and should be used freely. Daily sponging of the neck and thorax with cold water is beneficial, and appropriate light gymnastics should be instituted if the subject be old enough. In-door occupations are to be forbidden, and the ventilation of living- and bed-rooms must be looked after carefully.

Tuberculosis is apt to develop especially in children while convalescing from acute fevers, and hence during this period the child should be strengthened by vigorous feeding, pure air, and tonics. In children predisposition often results from obstructions in the nose and from

persistently enlarged tonsils; and they should be promptly removed. All local foci of tuberculosis in children—glandular, osseous, and articular—must be attacked surgically.

Treatment of the Disease.—The treatment of tuberculosis, regarded as a parasitic disease, presents two leading indications. One has reference to the destruction of the specific cause, the tubercle bacilli, by the use of antiseptic inhalations or of some parasiticide taken internally. Of the numerous substances used by inhalation, few have given satisfactory results, this being largely due to our inability to convey them to the smaller bronchi in a sufficient degree of concentration. They are best adapted to, and most efficacious in, cases in which the larynx is involved.

While the antiseptic treatment, both by inhalation and by means of the introduction into the blood of antiseptic substances, is to be carried out, it accomplishes nothing more than the arrest of the growth and development of the bacilli, and that in an indirect manner. The inhalation of antiseptic substances may be accomplished in various ways—by inhaling vapors, by the use of the steam atomizer, or by some form of “respiration-inhaler.” I have long employed the Robinson inhaler, the sponge of which is moistened with a few drops of a mixture made of equal parts of creasote, chloroform, and alcohol, the patient wearing the inhaler when not eating or sleeping. Unfortunately, most patients object to the constant use of this instrument. When hemoptysis is present, turpentine may be added to the above mixture. The chief among other antiseptics thus employed are carbolic acid, terebene and terpin hydrate, thymol, formalin, and oil of peppermint.

The most common, because least objectionable, mode of introducing this class of substances is by internal administration. According to the results reported from all quarters of the world, creasote thus employed alone enjoys the confidence of the profession; and in common with numerous other observers I have found its continued use to be followed by lessened cough and expectoration, lessened fever, and by a lessening or cessation of the night-sweats, with a gain of strength and weight as the natural consequence. It must be borne in mind that the dose is to be gradually increased to the point of gastric tolerance, which in my experience rarely exceeds 15 to 20 drops (0.999) three times a day.

Following, in the main, the practice of Trudeau, who has used this drug quite as extensively as any other American physician, after reaching the point of tolerance I gradually reduce the dose to and maintain it at 5 or 6 drops (0.333), three times daily. Among the best vehicles are hot milk, hot water, and diluted alcohol. Recently I have ordered it in capsules, which the patient himself fills at the *time of using*, and have found it a popular and ready mode of administration. When creasote is not well borne by the stomach and its inhalation is seriously objected to by the patient, it may be given by enema, the dose being 20 to 30 drops (1.332), in peptonized milk or mixed with a little egg-white. It has also been employed hypodermically in a 10 per cent. solution in oil of sweet almonds, the dose of which is 1 dram to 1½ drams (4.0–6.0). Lastly, it has in rare instances been employed by inunction.

Guaiacol, particularly in the form of the carbonate, has of late been quite extensively employed in place of creasote, of which it is the chief active principle. It may be administered in pill or capsule, the dose

being slightly less than that of creasote. It is well tolerated by the stomach, and is broken up in and absorbed from the intestinal canal.

Among other remedies prescribed for their supposed parasitocidal effect are arsenic and mercuric chlorid, but they are clearly inferior to creasote.

I am of the opinion that all antiseptics used internally in this disease have for their chief influence a modification of the soil-conditions on which the growth and multiplication of the bacilli depend. They are, in truth, of great value in fulfilling the second leading indication of treatment, which is to overcome the bodily receptivity for the specific bacillus, or to aid the natural defensive processes in limiting the destructive work of the latter. All forms of tuberculosis, however, may heal spontaneously in any stage, especially the local varieties so common in children, affecting the lymph-glands, joints, and bones.

Old pleuritic lesions, a large proportion of which are tuberculous in nature, are constantly met with at autopsies in persons dying suddenly of other diseases. Spontaneous recovery is seen oftenest in cases that have not progressed to the stage of cavity formation. Indeed, in the instances in which vomicae of considerable size have formed, cicatrization or complete cure is out of the question, though they may become encapsulated (quiescent). The percentage of cases in which encapsulated and obsolete lesions have been observed at the postmortem table in persons dying of all causes differs widely with the statistics of different observers. If we consider the cases that are latent from an early period in life, together with those of all ages after childhood, it is doubtless true that in more than 50 per cent. of the human family the bacilli effect a lodgment. Since about 14 per cent. of the deaths from all causes can be ascribed to tuberculosis, there must be manifested a strong tendency to limitation and healing.

In removing the diathesis medicines are unquestionably of less value than the hygienic treatment, the latter in the widest sense of the term aiming to reinforce Nature's efforts at spontaneous recovery, and embracing four main elements: (1) Climate; (2) Feeding; (3) Special Remedies; (4) Treatment of Leading Symptoms.

(1) **Climate.**—The all-powerful influence of environment has already been pointed out. Experience and observation have shown that certain climates, selected with particular reference not only to the stage of the affection, but more particularly to the individual, are useful modifying influences of the tissue-soil. In any case of tuberculosis that climate is most suitable in which the patient "feels well, eats well, sleeps well, and gains flesh and strength" (Delafield). Until the patient finds such a climate, or if he finds no single climate to produce these results, he should travel from place to place, unless special contraindications (excessive debility, etc.) exist. If active tuberculosis has existed, the stay in a suitable climate should not be less than two full years.

The climatic requisites for a consumptive are (a) purity of air, (b) equability, and (c) abundant sunshine. Less beneficial, though important, are (d) dryness and (e) altitude.

(a) *Purity of Air.*—This requirement is of paramount importance, and thus is explained the fact that mountain air and that of the virgin forest are so helpful in phthisis. Forests, and particularly pine-groves,

favor atmospheric purification, since they generate ozone, which oxidizes the impurities contained in the air.

(b) *Equability* has reference to the absence of rapid variations of temperature. On the whole, a relatively low is better than a high temperature, the former being stimulating, and the latter sedative, in effect. It should be pointed out that forests also greatly favor the quality of equability,¹ both as to temperature and relative humidity. They tend to maintain an almost unvarying degree of moisture in their vicinity, thus minimizing the diurnal variations of temperature—a point that is of far greater importance than the question of seasonal variations. Forests intercept and temper the bleak winds of winter, while by their shade and leaf-surfaces they afford a cooler temperature in summer.

(c) *Abundance of sunshine* is demanded by the consumptive. The advantages of sunshine are obvious from the observations made by Munn² in the year 1892, when in Denver there was sunshine in 62 per cent. of the possible hours during which it could occur. A *dry* atmosphere has advantages, but that dryness is not an essential element is shown by the fact that patients often do well at places having comparatively high relative humidity, such as Florida, Southern Georgia, Southern California, and the resorts on the south coast of England. The *rarefied* atmosphere of high altitudes, on account of its stimulating effect upon the respiratory function, aids in producing good results, but the pulmonary changes induced (enlargement of the air-cells, with augmentation of the size of the chest) make it necessary for patients to remain for the rest of their lives. That it is not an essential factor is shown by the excellent results obtained in the oftentimes purer atmospheres at lower levels. Cases in which hemoptysis is severe and of frequent occurrence, those complicated with weak hearts, and neurasthenic subjects should not be sent to the high altitudes.

The essential climatic factors mentioned are found in certain American and European resorts. Of the former, the Adirondack region, Colorado, Arizona, and New Mexico are especially to be mentioned, combining as they do in winter a uniform cold, much sunshine, and purity of atmosphere. A camp- or tent-life in the open air is strongly advocated. According to my own experience, the Adirondacks meet the indications best in early cases or in patients who have strength enough to lead an outdoor life, and in whom the breaking-down stage is not too far advanced. Some cases, in the early stage, also do well at Thomasville, Ga., Southern California, and at Lakewood, New Jersey. Some of these resorts possess the added advantage of affording an opportunity of gaining a livelihood. Among foreign resorts, Davos possesses about the same advantages as may be met in Colorado, New Mexico, and the Adirondacks, while the resorts in Southern Italy and France are comparable to Southern California, Southern Georgia, Florida, and the Bermudas in this hemisphere. Good culinary and home comforts are considerations of no less importance than the climate.

Briefly, the atmosphere of forest resorts possesses certain unmistakable advantages for this group of sufferers. Hence they should be sent into the neighborhood of the nearest forest in mild latitude (if they cannot enjoy the advantages of more remote resorts), where reasonably good

¹ *House-plants as Sanitary Agents; Sanitary Influence of Forest Growth*, p. 312, by the writer.

² *Medical News*, Aug. 18, 1894.

food and other comforts of life are obtainable. The superior value of the highly ozonized and terebinthinized atmosphere of the pine-groves in laryngeal tuberculosis cannot be too strongly emphasized.

Sanatorium Treatment.—While it is essential to send patients to suitable resorts, the most satisfactory results are obtained from the combined climatic and sanatorium treatment. Sanatoria are warmly advocated by Trudeau, Knopf, Bowditch, and others. They should take the form of cottages and pavilions. The principal advantages offered are due to a rigid system of hygiene under the close supervision of competent medical officers. There are *four groups of cases* among the middle and lower classes that require institutional treatment:

Group I.—The numerous cases that have progressed to an advanced and practically hopeless stage and the acute forms. These require every comfort and kind care, such as can be furnished by *special hospitals* for consumption in a healthful urban locality.

Group II.—Incipient cases among the pauper element. For these, sanatoria located close to large municipalities, though with special reference to such factors as purity of atmosphere and protection from chilly blasts, by natural elevations or the woodland, should be provided.

Group III.—Phthisis pulmonalis among the middle and working class, or persons having small means. The members of this group will find themselves compelled to depend principally upon private philanthropy, and probably to some extent also upon semi-State institutions; they need sanatorium treatment in the best climates, and there is no valid reason why the combined sanatorium and climatic treatment should not be attempted, since such an undertaking could be made almost self-sustaining.¹

Group IV.—“A settlement for patients with arrested consumption where they can be employed on work adapted to their strength” (Powell²).

Among *home sanatoria* are the Adirondack Cottage Sanatorium, the Sharon Sanitarium, near Boston, the Loomis Sanitarium, at Liberty, N. Y., the Winyah Sanitarium, at Asheville, N. C., the White Haven Sanitarium and Mont Alto in Pennsylvania. *Foreign sanatoria* are to be found at Falkenstein, near Frankfort-on-the-Main, Goerbersdorf, and Hohenhonnef. Solaria, in connection with city hospitals for advanced cases, would, I am certain, yield gratifying results. Home sanatoria can be readily improvised by stocking living apartments with growing plants. The beneficial influences arising from the presence of the latter are ascribable to two functions—the generation of ozone and transpiration.³ Tuberculosis dispensaries and classes are highly recommended in the treatment of tuberculosis among the poor and persons having small means.

Open-air Treatment at Home.—This method is now widely practised. It is of inestimable value to patients who must perforce be treated at home. They are kept constantly in the open air, and for the most part at rest. At night the bed-room windows should be open, even in severe weather. Indeed, sleeping in the open air on a veranda, porch, or the roof, is to be advised and encouraged, and ingenious contrivances have been invented whereby the patient can occupy a bed out-of-doors at all

¹ “Sanatoria and Special Hospitals for the Poor Consumptive and Persons with Slight Means,” by the writer.

² *Lancet*, Jan. 6, 1906.

³ *Ibid.*, by the writer, p. 168.

seasons of the year. With warm clothing, abundance of good food, especially raw eggs and milk, and a careful regimen, surprising results are obtained even in large cities. In my opinion, most tuberculous patients, at all events, require the rigorous discipline of a sanatorium for a variable period of time so that they may acquire proper habits of living. Such a sanatorium for the reception of indigent patients should be situated in their home climate. The experiment has already been made in Chicago and other cities with complete success. When the temperature is above 100° F. (38.7° C.) the patient should be kept at rest. Flick, Minor, and Coleman are of the opinion that tuberculosis patients can be successfully treated in their homes and other places than sanatoria.

(2) **Feeding.**—The diet should be both nutritious and generous. Too close attention cannot be bestowed upon the feeding. Above all, when the remedies prescribed (cod-liver oil, creasote) embarrass in the slightest degree the function of the stomach they must be stopped.

Such albuminous articles as milk, eggs, flesh, fish, and fowl, together with an abundance of fats, should be taken. The hydrocarbons are urgently needed, but they must be taken with care lest they derange the digestive function. Over-alimentation with raw eggs and milk is strongly advised. The eggs are to be slightly beaten and stirred into the milk and the quantity is to be increased until from eight to twelve eggs and as many glasses of milk are taken daily. One-half of this amount may be used during the morning hours and the other half during the evening hours. At mid-day a meal composed of easily digestible solids is allowed. In advanced cases it is often needful to resort to a rigid system of feeding, giving a small quantity of food, such as milk, meat-juice, egg-white, and the like, at brief intervals. The French method of forced feeding deserves a trial if there be absolute loathing for food. It consists of first washing out the stomach with cold water, and then introducing the following mixture thrice daily: 1 liter of milk, an egg, and 100 grams of very finely powdered meat. As a rule the patient cannot be induced to swallow this, and it then must be poured through a stomach-tube. In a minority of the cases the appetite is ordinarily keen, often as a result of change of air, and these usually pursue a favorable course. The following combinations will be found useful in assisting the appetite:

| | |
|-------------------|------------------------|
| R. Sodii bicarb., | ziss (6.0); |
| Tr. nucis vomicæ, | f3iiss (10.0); |
| Glycerini, | f3ss (15.0); |
| Inf. cascariillæ, | q. s. ad f3iv (120.0). |

Sig. 3ij (8.0) t. i. d., in water, fifteen minutes before meal-time.

Other simple bitters and mineral acids may be tried, and there are many cases in which the judicious use of stimulants, particularly wines and malt liquors, aids the appetite and digestion materially. The chief indications for the exhibition of alcohol are loss of appetite, feeble digestion, and weak, rapid action of the heart. Brandy or whisky in the form of milk-punch may be given freely in the advanced stage. Strychnin is a valuable remedy in the later stages. Lavage has helped some of my cases immensely. Lastly, an orderly method and sound judgment must be brought to bear in arranging the diet and drink.

(3) **Special Remedies.**—The treatment of tuberculosis by mercury has

been widely adopted. Wright¹ recommends the succinimidum, and the details follow: "One injection of hydrargyrum succinimidum, grain $\frac{1}{6}$, is given every other day until 30 injections have been given. Then injections are discontinued and potassium iodid, grain ij to x, is given well diluted with water one-half hour after meals for two weeks. Then potassium iodid is discontinued and no medicine is given for one week. Injections are then resumed as follows: One injection every other day until 30 injections have been given, on alternating injection days giving hydrargyrum succinimidum, grain $\frac{1}{6}$ and $\frac{1}{10}$, respectively. After the thirtieth injection the same course of potassium iodid is given as followed the first series of injections; then a week free from medication. The injections are then resumed again, the succinimide, grain $\frac{1}{10}$, being given every other day until 30 injections have been given. By the end of this third series experience will direct any necessary further treatment."

Cod-liver oil is another special remedy of great value. It sometimes causes further impairment of the appetite and digestion, or sets up intestinal disturbances, when its effects are harmful. The commencing dose should be small (3j—4.0, once or twice daily, to be increased after a time to 3ij—8.0, two or three times daily). It should be taken about meal-time. When the oil is not well borne, it may be given in combination with an alkali (lime, soda). As a substitute for cod-liver oil, cream, preferably Devonshire, may be tried (3ij to 3ss—8.0 to 16.0, three times daily).

The *hypophosphites* are especially serviceable in a certain proportion of the cases. The dose is 3j to ij (4.0—8.0) thrice daily, after food.

Arsenic is warmly advocated for its general influence in this disease. The dose should be small, so that it may be given for a long time without interruption. As sodium cacodylate, its use has increased of late. Jacobi speaks highly of digitalis in tuberculosis in children.

Iodoform- or *europhen-inunctions* are warmly commended by Flick, who asserts his belief that incipient cases almost always can be cured in this way, and that advanced cases can be improved.

Serum-therapy.—The definition of this term embraces also the employment of toxins and modified toxins produced in various media for the establishment of artificial immunity. Koch's tuberculin and Paquin's antitubercle-serum have been highly recommended as remedies in tuberculosis by certain clinicians. Dr. Trudeau prefers antitoxic immunity and considers tuberculin habituation its essential feature and the best guide to dose; this requires long-continued and almost imperceptible progression in dosage until a maximum is reached without causing general or local reactions. A. E. Wright recommends Koch's tuberculin, claiming that in patients so treated the formation of opsonins is stimulated, as shown by a remarkable increase in the phagocytic index. Penrose² first obtains a good tolerance dosage of tuberculin, then administers a course of succinimid of mercury, and later alternates the two remedies with a view to using larger doses of tuberculin without risk. Escoyer claims 53.8 per cent. of radical cures from the use of Cuguillere's serum.

Brauer, Wellman,³ and others recommend artificial pneumothorax in the treatment of selected cases of pulmonary tuberculosis.

The *advent of an acute disease* may arrest and cure a tuberculous process. Thus, the symptoms and signs of advanced tuberculosis have

¹ Jour. Amer. Med. Assoc., Nov. 28, 1908.

² New York Med. Jour., June 11, 1910.

³ Beiträge zur Klinik der Tuberkulose, Würzburg, Dec. 10, 1910, p. 2100.

disappeared after an attack of virulent small-pox and acute rheumatism (Harris and Beales). Hysteria also exercises an ameliorating effect upon pulmonary tuberculosis, according to the observations of Gibotteau,¹ who advises against treatment of the former disease in tuberculous persons.

Treatment of the Acute Forms.—The treatment of acute tuberculosis is an expectant one. The special measures recommended above should be tried, but are rarely effective, and a change of climate is inadvisable. Supportive measures, such as stimulants and nutritious aliment, are required. The medicinal treatment must be adapted to the acute febrile condition, but all depressants are to be avoided. Special symptoms may be relieved in accordance with general principles. In *renal tuberculosis*, recent experience confirms anew the importance of prompt nephrectomy.

(4) *Treatment of Leading Symptoms.*—(a) *Cough.*—This is often quite annoying. The special cause or causes of the coughing should be determined before any attempt is made to treat it. When attributable to catarrhal irritation of the upper air-passages, it is best treated by topical applications. The following substances may be inhaled: compound tincture of benzoin, combined with paregoric or carbolic acid; formalin; creasote, alcohol, and chloroform in equal parts. For local applications by means of the spray sedatives and narcotics should be preferred, and a solution of cocain is sometimes most efficient. The cause may be found in pleurisy or pleuritic adhesions, and for this condition counter-irritants, as iodin, sinapisms, etc., may be used. Pleuritic coughs often demand codein or even morphin in moderate-sized doses. The cough is in most instances occasioned by the tuberculous bronchitis, and to a lesser extent by the vomicæ. Cough-mixtures as usually formulated are apt to disorder the digestive function, and in so far as they have this effect they are positively harmful. Syrups should be omitted from their composition. Creasote by inhalation is the remedy *par excellence* for tuberculous bronchitis, combined with spirits of chloroform and alcohol. When expectoration is copious, preparations of terebene, terpin hydrate, and tar may be resorted to; and when the cough becomes distressing, I employ codein (gr. $\frac{1}{8}$ — $\frac{1}{4}$ —0.008 to 0.016, every three or four hours) in the form of a granule. In the later stages morphin is allowable, since it is at this time that constant coughing or severe paroxysms of cough, if not restrained lead to utter exhaustion. Heroin, in doses of gr. $\frac{1}{6}$ to $\frac{1}{12}$ (0.01–0.005), three or four times a day, acts beneficially in allaying the cough that accompanies phthisis. Stimulant expectorants may be needful, and ammonium carbonate in the infusion of wild-cherry bark is perhaps most efficacious: a few drops of the deodorized tincture of opium or spirits of chloroform may be added.

(b) *Fever.*—Creasote has found a new field of usefulness in the treatment of the fever of tuberculosis. In my experience at all events, the cases in which it has been used, as above indicated, have shown a greatly diminished febrile movement. Cold or tepid spongings of the body at intervals of one, two, or three hours, according to the intensity of the fever, should be tried. Internal antipyretics are rarely advisable, since during the period of high temperature the cardiac action is much enfeebled; but if urgently called for, the following may be employed: acetanilid (dose gr. ij–iij—0.129–0.194), phenacetin (gr. iij–v—0.194–0.324). These are to be administered about two hours before the com-

¹ *The Practitioner*, October, 1894.

mencement of the daily rise in temperature, and repeated every three or four hours if necessary. Other antipyretics worthy of trial are the mineral acids and zinc oxid, but not quinin, which has utterly failed in my hands. Keeping the patient at rest when there is fever is of the utmost importance, though he should be wheeled into the fresh air for as long a time as possible during the day.

(c) *The Night-sweats*.—Among remedies that control the sweats most successfully may be mentioned—atropin (gr. $\frac{1}{120}$ — $\frac{1}{60}$ —0.0005–0.001); zinc oxid (gr. ij–v—0.129–324); sulphuric or gallic acid; muscarin (Mijj–vj—0.399 of a 1 per cent. solution); agaricin (gr. $\frac{1}{8}$ — $\frac{1}{4}$ —0.008–0.016). Sponging with equal parts of alcohol and tincture of belladonna is very effective, but my own best results have been derived from the use of atropin (gr. $\frac{1}{120}$ — $\frac{1}{90}$ —0.0005–0.0007) in combination with agaricin ($\frac{1}{8}$ —0.008).

(d) *Dysphagia* may be a troublesome symptom, especially from involvement of the larynx, and it is best met by local applications of a solution of cocain in glycerin and water (gr. x to 3j—0.648 to 32.0), thrice daily before meals. In advanced cases I have resorted to hypodermic injections of morphin (gr. $\frac{1}{8}$ —0.008) before meal-time.

(e) *Gastric Disturbance*.—In nearly all cases of phthisis dyspeptic symptoms come on sooner or later, and for this gastric disorder nothing is so important as a proper regulation of the diet. Perhaps the medical treatment of the stomach symptoms has been dealt with at sufficient length, save that of vomiting, which may come on after meals and constitute a distressing concomitant. Those remedies giving the best results may be adduced as follows: cerium oxalate (gr. v–viij—0.324–0.518), in capsules before meals; calomel and soda in fractional doses; hydrocyanic acid (Mij–ijj—0.133–0.199); and chipped ice with brandy sprinkled over it, taken at short intervals, but especially shortly before meal-time.

(f) *Diarrhea*.—The most important factor in the treatment of this symptom is a properly restricted dietary. Alum whey, mutton and chicken essence are of service, but curds of milk, beef-tea, and solids are not suitable. Of the numerous medical measures that have been employed, the most useful are bismuth, acetate of lead, opium, thymol, salol, benzo-naphthol, and naphthalin. To these may be added the following acid diarrhea-mixture, each dose containing—

| | | |
|------------------------|-------------------|------------------|
| R̄. Acid. acetici dil. | m _x | (0.666); |
| Morphinæ acetat., | gr. $\frac{1}{8}$ | (0.008); |
| Plumbi acetat., | gr. j–ij | (0.0648–0.1296). |

Complications when they arise must be dealt with according to accepted therapeutic principles.

LEPROSY.

(*Lepra*).

Definition.—A chronic, contagious disease, caused by the bacillus lepræ. It is distinguished by constitutional depression and, pathologically, by tuberculous masses in the muco-cutaneous surfaces, and by changes in the nerves.

Historic Note.—In 1889, Morrow stated that in India alone there were certainly not less than 150,000 lepers, while at present it is estimated that there are over 250,000. Its geographic distribution probably covers more than one-third of the entire surface of the globe. It is common in Africa, Brazil, in the East, and in Norway. In the Sandwich Islands the disease is of comparatively recent origin, and yet of great and increasing prevalence, a leper settlement having been established consisting of more than 11,000 cases. Leprosy is not unknown in America, and in Mexico it has existed ever since the time of Cortes (Morrow). Blanc states that there are 75 to 100 lepers in Louisiana alone. It was introduced into California and Oregon by the Chinese, and into Illinois, Iowa, Wisconsin, and Minnesota by Scandinavian immigrants. It has been imported from the Sandwich Islands to *Salt Lake City*, and from Normandy to Tracadie on the Gulf of the St. Lawrence, where the "disease is limited to two or three counties which are settled by French Canadians" (Osler). Sporadic cases have been met with in most American cities. The Commission on Leprosy reported in 1902 the records of 278 cases, of which 145 were native born Americans. The disease appears to be lessening in the United States.

Pathology.—The bacilli grow and develop in clusters in the tuberculous nodules in the skin and in the anesthetic and pigmented areas, residing within the epithelioid cells and leukocytes. These so-called lepra-cells are probably derived from the lymphatic vessels or capillaries, having been transformed by the bacilli. Surrounding the granulomatous masses is a layer of connective tissue. The bacilli are also found in the lymphatic glands, the spleen, and liver, but rarely in the blood. The nodular tumors form projections from the skin-surface, and, being poorly supplied with blood-vessels, they soon undergo caseation and absorption or are obliterated by dense connective tissue (*facies leontina*). The pus-organisms generally exercise an influence in causing suppuration with ulceration, which may manifest a marked destructive tendency. Similar changes occur in the internal organs or in the mucous membranes.

Nerve-lesions are induced by the presence of the bacilli within and around the nerves. Here they set up an irritation with hyperesthesia (neuritis), leading to atrophy, with marked degenerative changes.

Etiology.—**Bacteriology.**—In 1880 Hansen discovered the bacillus lepræ, since proved to be the special agent of the disease. It strongly resembles the tubercle bacillus, but differential stains have been suggested by Unna and others. Bordoni-Uffredozzi was able to cultivate a bacillus which differed from the lepra bacillus in its morphology, although staining in a similar manner. His results have been confirmed by Czaplewski. Inoculation experiments on animals have not as yet succeeded.

Predisposing Causes.—Everyone is susceptible to leprosy. E. B. Goodhue, however, claims that a natural immunity exists. The disease is most frequent between the twentieth and fortieth years, and is rare in childhood. Sex and latitude have little if any influence. Hereditary transmission probably influences about one-fortieth of the instances (Zambaco). Heredity is denied by both Hansen and Raminéz. As pointed out by Bidekap, leprosy is often rare in large cities, even though prevalent in the surrounding rural districts.

Modes of Infection.—The disease is transmitted by contact; but

Widal and others, who have studied the disease as it exists in the Hawaiian Islands, think that leprosy is contagious only by inoculation. Morrow's view, that, like syphilis, leprosy is generally transferred by sexual intercourse, receives support. Hansen holds that the infection atrium is unknown; he thinks it probable, however, that the mouth and nasal cavities are the avenues of entrance. Sticker also regards the nasal mucous membrane as the primary focus and finds in it constant lesions. The bacillus has been found in the floors and walls of houses in leper colonies and also from the urine and even the milk of patients.

Clinical History.—Two forms are recognized, the *tubercular* and the *anesthetic*, while a third or mixed type is described by some authors. Neither of the first two, however, runs its entire course without developing into a third or mixed form.

The *incubation* is usually long (three to five years—Hansen). It may rarely be shorter or much longer. Vague *prodromes* are present for years (drowsiness, chilliness, recurring attacks of fever, debility).

(1) **Tubercular Form.**—In the first stage there is a patchy, cutaneous *erythema* with a slight hyperesthetic elevation of the affected areas (*macular leprosy*). These are oftenest seen on the face, the extensor surfaces of the arms and knees. They may vanish and leave the skin pigmented and anesthetic, and later the pigment may disappear, while white spots of corresponding size remain (*lepra alba*).

When the disease progresses less favorably tuberculous *nodules* (dusky red or almost brown in color) develop in addition to anesthesia. The small ones soon disappear, while the large ones are either absorbed or break down and ulcerate—changes which, as they advance together with the slow healing process, produce marked deformities. The *skin* is greatly thickened and presents a scaly surface, and there is loss of substance in certain parts, while others are enormously enlarged (eyebrows, nostrils, lips, etc.). Among the many symptoms pointing to involvement of the mucous membrane are *ozena*, *hoarseness* or even *aphonia*, and the signs of *inhalation-pneumonia*. Blindness often ensues as the result of extension of the process. To ulcers extending deeply into the mucosa of the pharynx and larynx, death may often be ascribed.

(2) **Anesthetic Form.**—In this variety the *local symptoms* point usually to implication of the nerves. At the onset there are *pain* and *patchy hyperesthesia*, while minute bullæ, due to trophic changes, put in an appearance on the arms and legs. The *muscles* supplied by the branches of the affected nerve-trunk waste, and the superficial nerves feel thickened and nodular. *Bright-red patches* of vaso-motor congestion appear and soon become anesthetic, while the maculæ disappear. *Anesthesia* may proceed without the latter eruption. Dry, yellowish-white, scaly patches upon the trunk and extremities are also visible. Early their centers alone are anesthetic, but subsequently the loss of sensation spreads even to healthy portions of the skin.

Trophic alterations reach an extreme degree. Bullæ appear, and, bursting, leave perforating or destructive ulcers, usually upon the extremities. As the result of absorption, wasting, and necrosis great deformities are produced. The hands often take on a claw-like form, and the fingers and toes may disappear (*lepra mutilans*).

Diagnosis.—The early diagnosis rests upon the presence of patchy

erythema with hyperesthesia, followed by the development of anesthesia, with a disappearance of the muscular eruption. Nodular neuritis is pathognomonic of anesthetic leprosy. Scrapings of the skin lesions frequently show the specific bacilli. In the advanced stages of either form confusion could scarcely arise. The nodular form of *tubercular syphilis* is distinguished by the distribution of the lesions, the history, the frequent sensory nerve-lesions, and by incising the tubercle and compressing serum from it—when lepra bacilli are found in the exudate—bacilli may be found in the nasal secretion. Zambaco and others have claimed that *syringomyelia* and *Morvan's disease* are in most cases but forms of leprosy; but this has been disputed by Hoffman, Schlesinger, and Sahli. Syringomyelia depends on lesions of the central nervous system, while leprosy has its nervous lesions in the peripheral nerves. The first symptoms in syringomyelia are localized usually in the upper extremities, while in leprosy they are generalized. In leprosy the tactile sense is usually lost, in syringomyelia usually not lost. Shoemaker and Boston¹ report an advanced case where lepra bacilli were found in the blood, and collected reports of 20 similar cases from the literature.

Prognosis.—Leprosy runs a very chronic course, lasting sometimes two, three, or more decades. The prognosis as to the final issue is hopeless, but the patient may live in comparative comfort for many years before the ravages of the disease cause great mutilation.

Treatment.—Certain diseases are supposed to exercise a retarding effect on leprosy (erysipelas, pneumonia, variola, phthisis). *Antagonistic inoculation*, however, as practised by Beaven Rake and others, has been practically negative in its effects; and the same is true of the treatment by Koch's tuberculin. The disease has thus far resisted all methods of treatment. Matthews² treated 7 cases representing both kinds of leprosy with x-rays and high frequency, and concludes that it is the only method which has produced any real effect on the progress of the disease. *Internally*, chaulmoogra oil has been employed by Berge and Phillippo with excellent results, the dose being from 1 to 2 drams (4.0–8.0). It is sometimes administered in pearls (each containing $\text{M}\bar{3}$ to 5—0.199–0.333), in ascending doses, until the limit of tolerance is reached. Surgical interference may become necessary. Manson advises free excision if only one tubercle, and no signs of a general invasion, be present. Segregation of lepers has been instituted in certain localities with encouraging results. Calmette's antivenomous serum, while not a true antidote, may produce a marked temporary improvement or even cure in uncomplicated cases. The Nastin treatment (dose 1 c.c. by injection) has given variable results.

GLANDERS.

(*Farcy.*)

Definition.—An infection of equine origin, caused by the bacillus mallei. Two forms are recognized—*true glanders* and *farcy*.

¹ *Proceedings of the Philadelphia County Medical Society*, Jan., 1903.

² "Treatment of Leprosy with x-rays and High Frequency," *Indian Medical Gazette*, Aug., 1908.

Pathology.—The characteristic lesions are new growths (granulomata, according to Virchow), which are usually nodular in character, though they may be diffuse. These masses soften and form ulcers when they occur on the nasal mucosa, and abscesses when they are situated subcutaneously. Microscopically, the nodular tumors are composed of cells—lymphoid and epithelioid—together with the specific bacillus.

Etiology.—The morbid changes above described are caused by a specific organism, the *bacillus mallei*, which resembles closely the tubercle bacillus, though it is a little thicker as well as shorter. It is non-motile. It can be readily grown, and as readily inoculated into horses, in which it produces the disease with every characteristic symptom. Perhaps the simplest method of staining the bacillus mallei “is to treat a cover-glass preparation with warm carbol-fuchsin (preceded by acetic acid), and then wash it off with a 2 per cent. solution of nitric acid.”

Modes of Infection.—The virus is, as a rule, transferred directly from the infected animal to man, hence the disease occurs almost invariably among males and persons who come in contact with horses (hostlers, coachmen, soldiers, veterinarians, and farmers). Transmission from man to man has been observed, but rarely. The medium of conveyance is either the pus or the nasal secretions, which may drop or be blown from the animal's nostrils upon a wound in the skin or mucous membranes, however slight, and be absorbed.

Immunity.—The disease is rare in man because of natural immunity. Singer has produced artificial immunity by intravenous injections of sterilized cultures of the glanders bacillus.

Clinical History.—The duration of the incubation-period is from three to five days, and rarely longer. Both glanders and farcy may be acute or chronic in their course.

(1) **Acute Glanders.**—At first the signs of inflammation develop at the point of infection, *lymphangitis* and swelling of the adjacent lymphatic glands being associated. Fever and other evidences of general disturbance soon appear, and at the end of two or more days the nasal mucosa becomes implicated, ulcers forming, from which a fetid muco-purulent (sometimes blood-streaked) discharge takes place. Nose-bleed is common. Later an eruption comes out on the face, the trunk, and the extremities, particularly about the joints. It is papular, quickly becoming pustular, and the pustules may dry up while fresh papules are developing—a characteristic feature. The face, particularly the nose, now swells, and a bluish-brown tumor covered with vesicles appears. Implication of adjacent mucous membranes—conjunctivæ, pharynx, mouth, etc.—is usual, and less frequently the bronchial and gastro-intestinal mucous membranes are involved. The ulcerative processes may extend to the bones, setting up necrosis. True arthritis occurs in 10 per cent. of the cases (H. Morel). Broncho-pneumonia is a common complication.

(2) **Chronic Glanders.**—A rare disease with mild but vague general symptoms, as muscular and arthritic pains, fever at intervals, asthenia, and progressive wasting, and the local features of nasal catarrh, with a bloody muco-purulent discharge. Cough may be present.

(3) **Acute Farcy.**—In this form the virus is inoculated into the skin, which presents the chief symptoms, the nasal condition being in abeyance or absent. The primary lesion is of an aggravated type, accom-

panied by numerous cutaneous boils and abscesses, often following the line of the lymphatics. Their favorite seat is in the vicinity of the joints. The constitutional symptoms simulate those of acute pyemia.

(4) **Chronic Farcy.**—Granulomatous tumors, resulting in abscesses, constitute the chief clinical peculiarity. The abscesses are situated primarily in the subcutaneous tissues, and often near the joints. As a rule they open spontaneously and discharge, first a thick, creamy pus, and later a thin, fetid material. They sometimes form distinct ulcers, extending in depth until the bones are involved.

The *general symptoms* simulate those of chronic glanders, the fever-curve being of the hectic type. In advanced cases emaciation and prostration become extreme. The *duration* varies from ten to eighteen months, though death may result earlier from some associated disease.

Diagnosis.—The diagnosis cannot be made without a clear history of contact with an animal known to be affected with the disease. In doubtful instances some of the suspected material should be injected into the peritoneal cavity of a male guinea-pig. Pus is soon formed in the tunica vaginalis testis and from it bacillus mallei may be recovered in pure culture. One of the products of the bacillus mallei is so-called "mallein," which has been used by Nocard and others as a diagnostic agent in animals. Its injection into horses suffering from glanders is followed by a febrile reaction. Schindelke found that a reaction of 3.5° F. (2° C.) is almost positive proof of glanders; while a rise of 1.25° F. (1° C.) is suspicious.¹

Differential Diagnosis.—Cases of acute glanders have been mistaken for *variola*; but the history of exposure, the mode of onset, nasal symptoms and the course of the eruption all differ from those of the latter disease. *Pyemia* may be eliminated by the history of exposure and inoculation experiments. The chronic forms must be distinguished from *tuberculosis* and *syphilis*.

Prognosis.—Acute glanders and acute farcy are almost invariably fatal. The chronic forms, however, and particularly chronic farcy, end in recovery, under appropriate treatment, in nearly one-half the cases.

Treatment.—The primary lesion should be dealt with surgically, and thorough disinfection followed by cauterization is highly recommended. Bayard Holmes advocates the opening of fresh abscesses and the scraping out of old ones under an anesthetic. A supporting plan of treatment, by generous feeding and judicious stimulation, is to be adopted, and the symptoms are to be met as they appear. The product, "mallein," has been recommended as a specific, but its curative properties have not yet been demonstrated. Bristow reports a case of human glanders treated by an autogenous vaccine, with recovery.

ACTINOMYCOSIS.

(“Big-jaw,” “Lumpy-jaw,” etc.)

Definition.—An infectious disease of cattle, less frequently of man, caused by the ray-fungus (*actinomyces*), which grows in the tissues, developing a mass with secondary chronic inflammation and metastatic growth as well as a secondary pyemic infection.

¹ Saunders' *Year-Book* for 1896, p. 1013.

Historic Note.—In 1877 Bollinger gave the first description of the ray-fungus, which he had observed in the disease known as “big-jaw” in the ox. Israel of Berlin discovered the fungus in man one year later. In 1879, Ponfick showed clearly that actinomycosis in man and cattle was one and the same disease. Murphy, who described the first case of actinomycosis hominis in America, states that up to the present date more than 500 cases have been reported.

Pathology.—A *macroscopic* mass is produced, consisting of a central fungous mass from which threads of mycelia radiate in all directions, producing the ray form of growth. Individual growths are of the size of a millet-seed, but their aggregation may result in masses as large as an orange; they are of a sulphur-yellow color and of tallowy consistence. Induration and infiltration may extend far into the surrounding tissues.

Microscopically, the little or single ray-like tumors show straight or wavy branching filaments (*supra*). Their development is accompanied by the growth of dense adjacent connective tissue. In addition, abscesses containing yellow granules in the pus occur, but these are secondary. The usual lesions are not the same as those described as occurring in beasts. In man the lesions consist of nodular growths with secondary abscess formation.

Bacteriology.—The organism of the disease belongs to the cladothrix variety of fungus, and may be cultivated, though with difficulty. The finer threads may readily be stained with anilin colors. The club-shaped projections, however, do not take these stains. Pus from whatever source should be examined for the actinomyces even though cocci are present. Rabbits and cows have been successfully inoculated. Pyogenic organisms are commonly in association.

Modes of Infection.—Infection generally takes place in young subjects through the mouth, teeth, and pharynx; and rarely the infection atrium is the air-passages or the skin. The infecting microbe is generally introduced with the food or drink, and Bostroem, from a study of 32 cases, concludes that the poison enters the economy by means of the ingested grains of some cereal (barley).

Clinical History.—(1) **Oral Actinomycosis.**—The patient often complains of *toothache*, *dysphagia*, and of *difficulty in opening the jaw*. The latter symptom may be owing to induration of adjacent muscles, and is a very characteristic sign (Partsch). At the angle of the jaw a swelling appears, which quickly passes into suppuration; later it opens (first externally, then into the mouth) and discharges pus containing little yellow masses. If not properly treated, extension of the process takes place in a downward direction, even to the abdominal organs.

The *upper jaw* may be the primary seat of infection, and if so the base of the skull may be perforated and the disease attack the meninges and brain. Bollinger has seen primary actinomycosis of the brain. In these instances caries of the spine may result from extension.

(2) **Pulmonary Actinomycosis.**—I am satisfied that primary pulmonary actinomycosis is comparatively rare, although Karewski and Butler have each recently reported an instance. In Butler's case the disease followed an injury by a falling board. The disease begins with *pain in the side*, often the left, due to *pleurisy*. There are *cough* and a peculiar (fetid) *expectoration*, together with general wasting. A microscopic

examination of the sputum, if made with care, reveals the *actinomyces*. In some instances the symptoms are identical with those of *disseminated tuberculosis* of the lungs (Brigidi), though generally the disease is unilateral. There is irregular fever, due to suppuration.

The **physical signs** may be those of chronic bronchitis merely; but there are, in not a few cases, extensive destructive changes of variable character (abscess, broncho-pneumonia, etc.), which modify the signs accordingly. In primary pulmonary actinomycosis an extension to adjacent organs and also metastatic growths and abscesses occur. Wood and Eshner¹ found the so-called sulphur granules in a pleural exudate of a case of pulmonary actinomycosis.

(3) **Intestinal Actinomycosis.**—The condition may be *primary* or *secondary*. The organism grows upon the mucosa of the intestine and excites a proliferation of the underlying connective-tissue cells, and the formation of submucous nodules. The latter ulcerate, and perforation of the serous coat of the bowel may occur, inducing peritonitis. Pericecal abscesses have been formed in like manner.

The **symptoms** point to intestinal catarrh, there being some gastric disturbance, with recurring attacks of diarrhea. The actinomyces has been detected in the stools. Secondary metastatic growths (rarely) and abscesses may arise in other organs (liver, spleen, ovaries, etc.). The viscerae may also be the primary seat of infection.

(4) **Cutaneous actinomycosis** rarely occurs. The skin presents chronic suppurating ulcers which show the presence of the ray-fungus, and the condition bears a close resemblance to a lupus patch.

Diagnosis.—This rests solely upon the finding of the actinomyces. The wooden hardness of the tissues beyond the borders of the ulcers or sinuses, the hardness of the neighboring muscles in oral actinomycosis, and the yellow granules in the pus are all significant, but merely corroborative. To detect the actinomyces, says Warren, sections may be stained with Ziehl's carbol-fuchsin from fifteen minutes to half an hour, and then decolorized in a 1 per cent. picric-acid solution until the whole section has a yellow appearance. Dehydrate and mount. The fungus appears as a brilliant red aster, while the surrounding tissues are yellow. The points mentioned above will serve to distinguish this disease from *tuberculosis*, *syphilis*, *chronic pyemia*, and *sarcoma*. Widal² differentiated actinomycosis by the sero-reaction in 8 cases.

Course and Prognosis.—The course is chronic. Mild cases may recover in from six to nine months or earlier, the oral form being perhaps the most favorable. Pulmonary actinomycosis may terminate in recovery, though rarely. Death usually results from pyemia, amyloid degeneration, and wasting.

Treatment.—This is mainly surgical. The removal of the parts involved and disinfection with acid-sublimate solution are the best measures. Billroth in a case of abdominal actinomycosis communicating with the bladder effected a cure by the use of fifteen tuberculin injections. Internally, the potassium-iodid treatment, as first recommended by Thomassen in 1885, and recently emphasized by DaCosta,³ is often attended with success when decided iodism is produced.

ANTHRAX.

(*Malignant Pustule; Splenic Fever; Wool-sorter's Disease, etc.*)

Definition.—An acute, infectious disease, caused by a special bacillus and clinically accompanied by the development of a characteristic pustule (boil) and blood-poisoning (*external anthrax*). The disease likewise affects the gastro-intestinal tract and the lungs (*internal anthrax*). Both forms are derived principally from the herbivora, it being especially prevalent among sheep and cattle. The occurrence of anthrax in the United States is much more frequent than has been held to be the case.

Pathology.—Post-mortem rigidity is marked. The blood is dark and thick and coagulates poorly, and in it, particularly in the spleen, as well as in the liver, kidney, and lungs, one may find the spores.

Besides the local lesions of the skin (*i. e.* ulceration, gangrene, edematous infiltration), and besides the degeneration of the heart, kidneys, and liver that is common to the severe and rapid infectious diseases, the especially striking lesion is the constant and great splenic enlargement.

The bowel may show hemorrhagic infiltration and gangrene, and the mesenteric and retroperitoneal glands may be enlarged and hemorrhagic.

Etiology.—**Bacteriology.**—The special agent is the *bacillus anthracis*. Gratia and Jonne give as the microscopic characteristics of anthrax, as seen in the blood, the following: (1) The anthrax bacillus has the form of a rod of a length varying from 5μ to 20μ , and in breadth from 1μ to 1.5μ . It is broken up into short articulations from 1.5μ to 2μ long, placed end to end like the sections of a tenia, the ends of each articulation being slightly swollen, giving the appearance of a bamboo cane; (2) clear spaces, appearing like a biconcave lens, exist between the ends of the articulations, and result from the slight concavity of these ends; (3) a capsule, often distinctly marked, surrounds the rod, seeming to form a protoplasmic support for the individual articulations. These threads of anthrax bacilli stain best with Löffler's blue. They grow readily on various media (agar, gelatin, potatoes, etc.) into interlacing thread-like filaments which distinctly show spore-formation, the threads assuming the appearance of strings of beads. They resist desiccation, many of the germicides, and boiling water even for a few minutes. Inoculations are followed by the production of the pustule of anthrax. Conradi¹ affirms that it is highly improbable that the anthrax bacillus produces a toxin.

Modes of Infection.—The *virus* (spores) gains entrance into the human body through the skin (slight wounds, abrasions, or scratches), the intestines (with food), or through the lungs (rarely). The sting of insects (mosquitoes, flies) may also transfer the poison to man.

Predisposing Causes.—**Occupation** is most influential: persons who come into direct contact with infected animals (hostlers, butchers, shepherds), and workers in factories who handle the hair or hides of such animals, being liable.

Immunity.—Pasteur's well-known protective inoculation with attenuated virus has been extensively practised in anthrax localities, with very favorable results. Peterman, however, reinvestigated the question of immunity by the albumose of anthrax, and found it without protective

¹ *Zeitschrift für Hyg.*, June 14, 1899.

action, except in the case of cultures on ox-serum, which, when injected in large quantities into the veins, conferred temporary immunity.

Clinical History.—The period of incubation is from one to three days. Two leading clinical types are distinguished:

(1) **External Anthrax.**—(a) *Malignant Pustule.*—At the point of infection (the hand, arm, neck, or face, or other exposed part) a small *papule* first appears, and develops into a *vesicle* of considerable size with bloody contents. This vesicle breaks, leaving a characteristic dark-bluish or black *scab* (anthrax), and encircling the primary vesicle an areola of miliary vesicles may be noticed. The base of the original vesicle now becomes swollen and indurated, and this brawny edema spreads rapidly to the adjacent tissues until an extensive area is involved. The neighboring *lymph-glands* may or may not be inflamed; if so, they are apt to be connected with the pustule by red lines (lymph-vessels, veins).

Severe *general disturbances* accompany the local disorder in the course of a couple of days, and comprise fever, decided prostration, sweats, splenic enlargement, and delirium tending toward coma. If recovery occur, the edematous swelling subsides and the black scab is cast off. In unfavorable instances collapse develops, and the case ends fatally between the fourth and eighth days. In such instances intestinal symptoms (diarrhea) or nervous phenomena of aggravated type may attend.

(b) *Anthrax Edema.*—In a certain proportion of the cases the *systemic infection* is out of proportion to the *local disturbance*, the latter consisting of an edematous swelling without the presence of an eschar. The eyelids (commonly), lips, tongue, and upper extremities may be the seat of extensive swelling, though there is no change in the color of the skin. This is a dangerous condition, and may result in gangrene.

(2) **Internal Anthrax.**—(a) *Intestinal Mycosis.*—In this form certain general, indefinite symptoms are the primary features, such as headache, pains in the limbs, anorexia, languor. Soon acute gastro-intestinal features supervene, sometimes preceded by a chill. As a rule, vomiting occurs, followed by abdominal pains and diarrhea, and the stools often become bloody. Hemorrhage may also occur from other outlets. Other symptoms, as dyspnea, marked cyanosis, and restlessness, are noted, followed sometimes by stupor, general convulsions, or spasms of single muscles or groups of muscles. There is moderate fever, and the spleen is enlarged. Death is preceded by collapse.

Interesting *epidemic* outbreaks of internal anthrax have occurred, due both to drinking-water derived from infected wells and also to diseased meat. Murisier has related the history of an epidemic in which 200 persons fell ill after eating meat from a certain cow. The animal was quartered by a butcher who had previously slaughtered an ox afflicted with anthrax, and had not disinfected his instruments; four days after this 25 persons were attacked by the disease.

(b) *Wool-sorters' Disease.*—This occurs among the operatives in factories in which imported wool or hair, mostly from Russia and South America, is sorted, and to produce the typical affection the infection must be swallowed or inhaled in the form of dust. *Mixed cases*, or those showing both external and internal anthrax, may be met with among workers in curled-hair establishments and the like. The *onset* is sudden, with a chill that is accompanied by pains in the back and legs, prostration,

and a sharp rise of temperature to 102° or 103° F. (39.4° C.). The *local* symptoms may either be chiefly pulmonary or gastro-intestinal. The former consist in dyspnea, chest-pains or feelings of constriction, cough, and rarely the physical signs of bronchitis; the latter comprise vomiting and a diarrhea that is followed by collapse, with marked lividity. Nervous symptoms, delirium, convulsions, or coma are often prominent in serious forms; but a fatal ending may occur while the mind is unclouded. The *course* ranges from one to five days.

(c) *Rag-pickers' Disease* ("Haderkrankheit").—This has been identified by Eppinger as the same form of disease as "wool-sorters' anthrax." It occurs among the rag-sorters in the paper-mills near Graz. Infection occurs in the respiratory tract. The symptoms observed are high fever, followed by collapse, with depression of the body-heat, painful and paroxysmal cough, cyanosis, very weak heart, together with the signs of pleuritic effusion and consolidation of the lung.

Diagnosis.—The history (occupation, etc.) and the appearance of the malignant pustule in external anthrax leave little room for doubt. The diagnosis, however, should be confirmed by an examination of the contents of the pustule for the presence of bacilli, and if found they should be cultivated and inoculated upon a guinea-pig or rabbit.

Internal anthrax may be suspected if the more characteristic pulmonary or gastro-intestinal symptoms, together with those of systemic intoxication, develop in persons whose occupation entails exposure. In doubtful cases the presence of bacilli in the blood must be shown.

Prognosis.—In external anthrax occurring in healthy persons the disease often pursues a favorable course; moreover, radical surgical measures have decreased the death-rate decidedly. Internal anthrax, however, is a deadly affection. As regards "wool-sorters' disease," those who survive for one week usually recover (Bell).

Treatment.—Prophylactic measures embrace the sterilization and destruction of the hair, hides, wool, etc., of infected animals as well as the cremation of their bodies. Subsequent disinfection of the infected premises and the prohibition of grazing in infected pastures are matters of the utmost importance. In the carbuncular form, if seen early, the best treatment is excision of the affected area, including a considerable amount of surrounding skin. In the edematous variety, early excision followed by cauterization is indicated. If impossible, as is the rule, injections of carbolic acid in a solution of water and glycerin (1:10) into the surrounding tissue have given the best results. Hallopeau recommends that in order to prevent extension the neighboring structures be bathed with a 10 per cent. solution of carbolic acid (first dissolved in alcohol) in oil or glycerin. Internally, stimulants, antiseptics, and nourishing food constitute our chief reliance. In internal anthrax efforts at treatment avail nothing. Several sera have proved valuable in the treatment of anthrax, the best being that of Selavo, which is obtained from the sheep or ass (Emery).

HYDROPHOBIA.

(*Rabies.*)

Definition.—A specific, infectious disease peculiar to carnivora and to a less extent to herbivora, which may be communicated to man by direct inoculation. It is characterized by slight fever, spasm of the

larynx and pharynx, delirium, a short stage of paralysis, coma, and, in the great majority of cases, a fatal termination.

Pathology.—The facies, pharynx, and esophagus may be congested, the latter organ being sometimes markedly edematous; pulmonary congestion has also been noticed. The mucous membrane may show here and there points of hemorrhage, and Fitz has observed blood-extravasations into the perivascular spaces of the brain. Soft thrombi may fill the cerebral vessels, especially the veins, while the blood has a dark color and its clots lack firmness.

Balzer, Benedikt, Kolesnikoff, and Schaffer made studies of the changes in the nervous system. Later, Babes described the "*tubercles rabiques*," which consist of pericellular accumulations of embryonal cells, the latter finally taking the place of the destroyed cell. More recently Van Gehuchten and Nèlis discovered lesions in the cerebro-spinal and sympathetic ganglia; they "consist in the atrophy, the invasion, and the destruction of the nerve-cells brought about by new-formed cells derived from the capsule, which appears between the cell-body and its endothelial capsule. These new-formed cells increase in number, invade the protoplasm of the nerve-cell, and finally completely occupy the entire capsule." Rarely, the kidneys may show cloudy swelling.

Etiology.—Pasteur has found the poison abundantly present in the nerve-centers, and has transferred the disease by taking bits of brain-substance or medulla derived from an infected animal and inoculating them into healthy subjects.

Bacteriology.—The micro-organism of the disease has not yet been determined, though Spenelli, Rivolta, Foll, Ferran, and others have described a bacillus. Memmo¹ believes he has established its claims as the specific organism, and reports successful production of the disease in dogs, rodents, and birds, with the typical differences characteristic of each.

The usual *mode of infection* in man is through the bite of a rabid animal, the virus being contained principally in the saliva, and in an immense majority of cases (about 90 per cent.) the dog is the offending party. The cat, wolf, cow, and horse also suffer from the disease, and in rare instances they communicate the disease to man. The skunk is also liable, and its bite has often transmitted rabies, especially to persons sleeping in the open air or in tents which the animal can enter. The virus gains access to the system through the broken skin.

Susceptibility to the poison exists in about one-half the instances in which persons are bitten by rabid animals, though in some cases this apparent immunity may be owing to slight or even non-infection.

Clinical History.—The *incubation-period* lasts from six weeks to three or four months, though in young subjects and in cases in which the infection is severe the symptoms develop earlier. Certain *prodromal symptoms* are manifested, as a rule, and generally last only a day or two; I have, however, seen two instances in which melancholia, due probably to the dread of what might follow, showed itself immediately after the reception of the bite and persisted. The usual premonitory symptoms are headache, loss of appetite, sleeplessness, great depression of spirits, and sometimes darting pains that radiate from the seat of

¹ *Centrabl. f. Bakt., Abt. i., Bd. xx., 17, 18.*

the bite. The adjacent lymph-glands may become swollen, and slight difficulty in swallowing is experienced.

Following the *invasion* are two stages: (1) **The Stage of Excitement.**—The patient wears an expression of the most intense anxiety. Hyperesthesia is present and attains to a marked degree, and the special senses exhibit the keenest vigilance, a noise or a draft of air often causing great psychic disturbance or a violent reflex spasmodic contraction of the larynx. Quite early the mere sight of water is dreaded by the patient, and forms a characteristic feature of the disease. This symptom has given the name hydrophobia to the disease, and springs from the fear of inducing a painful spasm of the larynx. The patient has thirst which he cannot assuage. There may be maniacal excitement, and the spasmodic contractions of the larynx may become so strong as to excite urgent dyspnea, with the emission of curious sounds. The muscles of the mouth may also exhibit convulsive movements, causing the patient to make snapping sounds; these, however, are secondary. There is associated great restlessness, with frequent lateral rolling of the head, and foaming saliva may be ejected from the mouth. The symptoms occur in paroxysms, and during the intervals the patient is generally free from excitement. There is fever as a rule, the temperature ranging from 100° to 102° F. (37.7°–38.8° C.) or over, but it may be absent; the pulse is moderately accelerated and is sometimes irregular, and toward the end of this stage the reflex spasms of the respiratory apparatus develop spontaneously. Mental aberrations and melancholia may ensue, and often lead to suicidal tendencies.

(2) **The Paralytic Stage.**—In the concluding stage the patient passes into actual unconsciousness or coma, without spasms. This lasts from twelve to eighteen hours, ending in death.

In man there is a *paralytic form* of rabies, but it is rare as compared with the delirious or psychic type. Thirty cases have been reported by Gamaléia, and it is apt to follow deep and multiple bites. The paralysis begins near the part bitten, and spreads until it becomes general, finally involving the respiratory centers. In rodents quiet madness ("dumb rabies"), without maniacal excitement, is the rule.

Diagnosis.—The hyperesthesia, the fear of water, the reflex spasms on attempting to swallow, accompanied by dyspnea and great mental agitation, form a very characteristic grouping of symptoms. Bits of brain-substance or medulla of the rabid animal that has inflicted a bite should be quickly obtained, and a subdural inoculation of a rabbit be made. If virulent, the paralytic form of the disease will ensue in from fifteen to twenty days. Ravenel and McCarthy,¹ following the method²

¹ *Proc. Path. Soc. Phila.*, March, 1901.

² This is as follows: The ganglion is put at once into absolute alcohol, in which it is left for twelve hours, the alcohol being changed once. It is transferred for one hour to a mixture of absolute alcohol and chloroform; next put for one hour into pure chloroform; then for one hour into a mixture of chloroform and paraffin, and lastly in pure paraffin for one hour. The sections are put in the oven for a few minutes, then passed through xylol, absolute alcohol, and 90 per cent. alcohol, after which they are stained for five minutes in methylene-blue according to Nissl's formula, differentiated in 90 per cent. alcohol, dehydrated in absolute alcohol, and cleared in essence of cajuput and xylol. Ravenel and McCarthy found that the capsular changes were best brought out in sections stained by hematoxylin and eosin. Since these latter changes are the most essential diagnostic features in the sections, they suggest that material unfit for the Nissl method will still show the capsular changes when stained by hematoxylin and eosin.

of Van Gehuchten and Nèlis, conclude that when present the capsular and cellular changes in the intervertebral ganglia, taken in connection with the clinical manifestations, afford a trustworthy means of diagnosis of rabies in the animal. When these changes, however, are absent (as happens in early stages of the disease), rabies cannot be excluded. *Hysteria* may be misleading, but here the previous history suffices.

The name *lyssophobia* has been given to cases that simulate, but have no relation to, hydrophobia, and Mills has advanced the warning that, however suggestive the symptoms following a dog-bite, the given case cannot be assumed to be a case of hydrophobia until other possibilities are excluded. It is highly probable that there is a form of hydrophobia which is the result of the wide publicity given to genuine and suspected cases alike. The characteristic symptoms may be present, but the affection does not develop. This so-called *pseudo-hydrophobia* appears only in neurotic and hysteric subjects. Recovery is the rule. Burr reports an interesting case of the kind that occurred in Osler's clinic, attended, however, with recovery.

Prognosis.—Few if any cases of rabies in man recover if the disease be allowed to develop.

Treatment.—**Prophylaxis.**—Upon the reception of a bite thorough disinfection, followed by cauterization of the wound with caustic potash, or, better still, excision, if important structures be not involved, is a measure that can be quickly carried out. The wound is then to be kept open for a period of four or five weeks. Dudley advises that a tourniquet should be applied if the bite be on an extremity. Systematic muzzling of dogs is to be encouraged and advised.

Preventive inoculation as perfected by Pasteur is a precautionary measure of the utmost importance. He showed that the virulence of the virus which is obtained from the nervous system undergoes modification by passage through animals. Thus the potency of the virus is increased by its inoculation from rabbit to rabbit (by placing bits of spinal marrow beneath the dura mater), the period of incubation at the same time growing shorter, till at last it is but seven days. On the other hand, the virulence is decreased or attenuated as the result of similar experiments upon the monkey. Pasteur also found that if fragments of the spinal cord were suspended in a dry atmosphere they lost gradually their virulence and finally became inert. From these an emulsion is prepared which is employed in the antirabic inoculations in man. In this way he secured a virus of known and reliable strength, and with this he could readily render the dog refractory by inoculating with very weak virus; then, by increasing from day to day the virulency of the inoculations, complete immunity was established.

Protective Inoculation.—"The patients are first inoculated with a cord fourteen days old, and the inoculation is repeated daily for nine days, each time with a cord one day fresher. In winter the oldest cords used are five days old, and in summer cords that have been drying for four days are also employed" (Warren).

For patients who have been bitten on the face, hands, or bare feet, as well as for those who have been bitten long before commencing treatment, the special preventive method, the so-called "intensive treatment," is applicable. Briefly, this consists in eliminating some of the inocula.

tions of intermediary strengths, thus lessening the number of injections, and also in administering the latter at shorter intervals than in the usual method of treatment. The success of the Pasteur method is universally attested. Pottevin gives the following summary of figures from the Pasteur Institute: From 1886 to 1894, 13,817 persons were bitten, with a mortality of 0.5 per cent. In the New York Pasteur Institute, 313 West Twenty-third Street, under the directorship of Paul Gibier, of 1367 cases treated during the decade ending Jan. 1, 1900, 19 died—a mortality of 0.66 per cent. The patients should be sent to the Pasteur Institute at once, since delay diminishes the protective power of the inoculation.

The established affection defies all known methods of treatment. Our aim should be to diminish the intensity of the painful spasms and the psychic disturbances. The patient should be isolated from sounds, light, and excitement of every sort. Food, as a rule, must consist of nutrient enemata, though by the local application of cocain the sensitiveness of the throat may be diminished sufficiently to enable the patient to take liquid nourishment (Osler). For controlling the spasms chloroform by inhalation is most effective; chloral internally and morphin hypodermically may be of advantage. The patient's anxiety is best relieved by a cheerful demeanor on the part of the attendants.

TETANUS.

(*Trismus*; *Lockjaw*.)

Definition.—An acute, infectious disease caused by the tetanus bacillus. It is characterized by painful spasms, affecting first and chiefly the muscles of the jaw and neck (*trismus*), and secondly those of the trunk, especially the extensors of the spine and limbs (*opisthotonos*). Two varieties are recognized: (a) idiopathic (?); (b) traumatic. In certain institutions and certain localities it occurs endemically, and among newborn children and the colored race it may prevail epidemically (*trismus neonatorum*). The incidence of the disease, however, is decreasing.

Pathology.—No constant post-mortem lesions have been found. The virus acts principally upon the nervous centers of the medulla and the cord, producing inflammation (and sometimes softening) of the gray substance of the cord. According to Brown-Séquard, the characteristic lesions are consequent upon an *ascending neuritis* starting from the wound, and it is true that the nerves often present traumatic lesions with redness and swelling of the neurilemma. Tetanus neonatorum often shows inflammation of the umbilicus.

Etiology.—**Bacteriology.**—In 1884, Nicolaier discovered the bacillus of tetanus, and in 1886, Rosenbach first found it in man. It is a long, slender rod, at one end of which appears a swelling due to the formation of a spore in that locality, thus giving the organism an appearance like that of a pin or drumstick. The bacilli are easily stained by Abbott's method, and are purely anaërobic. Pure cultures can be made, but with difficulty, since they will not grow in the presence of the smallest amount of oxygen. If pure cultures are injected into animals, typical

tetanus follows. Brieger has obtained two poisons from sterilized cultures of the bacillus in the pure state, and termed them "tetanin" and "tetano-toxin"—both most virulent poisons in the minutest quantity. These alkaloidal substances produce the tonic convulsions; hence tetanus is purely toxic in nature—an intoxication. The bacilli are most probably limited to the point of infection, and here develop the *toxin*, which "is carried mostly along the nerves to the spinal cord" (Stintzing).

Tiberti whose experiments corroborate those of Meyer and Ransom, found that the toxin is transported to the nerve-centres through the plasma of the nerve-fibers, but that the normal integrity of the axis cylinders to effect the conduction is preserved.

Modes of Infection.—In the outer world tetanus bacilli are found to be both numerous and widely distributed. They abound in the earth (garden-soil in particular), putrefying liquids, manure, in rubbish, and dust of streets and houses, etc. The fact that the bacillus of tetanus is anaërobic explains why it is most apt to follow punctured and contused wounds. An analysis of 1201 cases by the writer and A. C. Morgan¹ affords convincing proof that every case is the result of the introduction of the tetanus bacillus through a lesion of the skin, however minute it may be, and that so-called idiopathic or "rheumatic" tetanus does not exist. The presence of the bacillus in vaccine has apparently been the cause of some recent cases. The *locality* of the injury is most commonly on the extremities, particularly on the hands and the feet, although the figures of Anders and Morgan (previously cited) indicate the great susceptibility of all portions of the body to the poison.

Certain Predisposing Causes.—1. Males are more susceptible than females (*e. g.*, out of 981 cases the former sex made up 79.3 per cent.), although males are more exposed to infection. 2. The robust are more receptive than the weak, and the nervous than the lymphatic. 3. Season. In 687 cases the seasonal occurrence was recorded by Morgan and myself and indicated that tetanus is more prevalent in the hotter as compared with the colder months of the year. The maximum number of cases occurred in July (4th of July tetanus). 4. Age. An analysis of 583 cases, with reference to liability according to age, gave 229 cases, or 39.3 per cent. from the fifth to the fifteenth years of life, 145 cases, or 24.9 per cent. from the fifteenth to the twenty-fifth years, while there were 86 cases, or 14.8 per cent. between twenty-five and thirty-five years. After the fiftieth year only 14 cases occurred.

Immunity.—Behring and Kitasato have rendered animals immune by the injection of cultures of the bacillus after the addition of iodine trichlorid to diminish their strength, and this serum has been successfully used to protect others against tetanus.

Clinical History.—The duration of incubation depends upon whether the given case pursues an *acute* or a *chronic* course. In acute tetanus it lasts from one to two weeks, while in chronic the first symptoms usually appear after the second week. In so-called idiopathic tetanus the symptoms appear shortly after exposure to the special causes.

Symptoms of Acute Tetanus.—(1) Mild prodromal symptoms (languor, headache, etc.) may precede the more intense characteristic phenomena, which develop gradually. At first the patient complains of stiffness

¹ *Journal of the Amer. Med. Assoc.*, July 29, 1905.

and tension in the muscles of mastication and back of the neck, and soon tonic spasm of the masseters renders the facial muscles more or less immobile and locks the jaws (*trismus* or *lockjaw*). The rigidity of the cervical muscles is shown by the retraction of, and by attempts at raising, the head. The physiognomy is distinctive; it is immobile, the forehead being often wrinkled and the corners of the mouth retracted, producing a peculiar smile (*sardonic grin*). Next the muscles of the body become rigid, first the trunk (*orthotonos*), and then the spine is bent or bowed and the convexity presents anteriorly (*opisthotonos*). Lateral arching of the body also occurs, though rarely (*pleurosthotonos*). The belly-muscles are hard and board-like, and their contractions may throw the body forward (*emprosthotonos*). The arms generally remain movable, but the legs may be rigidly extended. The position of the body is one of constant rigidity, but from time to time convulsive seizures of variable duration occur, causing most agonizing suffering, thoracic oppression, dyspnea, and more or less cyanosis, due to interference with the respiratory function (especially spasm of the glottis). Sharp, lancinating pains occur at the base of the chest. "Convulsive dysphagia" (as in hydrophobia) is rarely observed. These spasms are usually reflex. The reflexes are increased. Rostowzew thinks that Kernig's symptom is an early and constant one in tetanus. The intellect remains clear. Profuse perspiration is a significant symptom.

Fever of a moderate degree is generally present. The temperature, however, may suddenly leap to 110° or 112° F. (43.3°–44.4° C.), forming an ominous symptom, these extreme elevations of temperature being probably due to paralysis of the centers that regulate bodily heat. Conversely, fever may be absent throughout the attack, and a brief post-mortem rise of temperature be seen. The *pulse* is quickened, and in the worst cases may become very rapid (140 to 160 beats per minute), small, and irregular. The *urine* may be suppressed or its passage impeded by the muscular contractions. The bowels are constipated.

(2) **Chronic Tetanus.**—The same symptoms are manifested as are seen in the acute form, but the condition does not progress so rapidly. In some instances the symptoms soon become aggravated, to be followed, however, by periods of decided relief from the painful spasms, so that during the latter the patient's strength can be maintained by means of stimulating food, and intervals of partial freedom from the excruciating pains grow longer in favorable cases, until finally the period of convalescence may be reached. *Relapses*, however, are common.

(3) **Cephalic tetanus** (first described by Rose) usually follows injuries to the head (face). Its most characteristic symptoms are rigidity of the masseter muscles, spasm of the pharyngeal muscles, causing dysphagia, chronic contraction of the muscles of the neck and abdomen (rare), and paralysis of the facial nerve on the same side as the injury. The latter symptom is due to local infection by a toxin. Recovery takes place in about 25 per cent. of the instances, according to Willard's statistics.

Diagnosis.—In view of the usual history, the predominating feature—trismus—together with the early appearance of rigidity at the back of the neck, will, as a rule, render the diagnosis a simple one.

Strychnin-poisoning must be eliminated, in which the following table will assist:

TETANUS.

Reception of a wound, generally followed by a period of incubation.
Begins with lockjaw; later spreads downward (the arms and hands escaping).

Reflex spasms not present at the outset.

Rigidity is persistent, except in the chronic form.

The course is prolonged into days or weeks.

Cultures made from the discharges of the wound show the *bacillus tetani*.

STRYCHNIN-POISONING.

Ingestion of strychnin, followed immediately by the symptoms.

Begins with gastric disturbance or a tetanic contraction of the extremities. Hyperesthesia of the retina occurs and objects look green.

Violent convulsions present from the onset.

Intervals of complete relaxation occur.

Course is brief, terminating in death or recovery.

Examination of the gastric contents shows strychnin.

Tetany gives rise to a prolonged spasm affecting the extremities (hands in particular) and the larynx, with intermissions; it is also characterized by a peculiar posture, and occurs chiefly in the young.

Hydrophobia is discriminated from tetanus by the history of a bite from an animal, by the predominance of the reflex spasm of the respiratory apparatus, by the intensity of the psychic disturbance, and by the absence of lockjaw and opisthotonos.

Course and Prognosis.—In the acute form the course is brief, and the prognosis is most unfavorable. "Acute tetanus or that which developed within ten days gave a total of 568 cases and a mortality of 74 per cent. On the other hand, 211 cases lasted over fifteen days, with only 18 deaths, or 8.5 per cent. mortality" (Anders and Morgan). Death results from asthenia, heart-failure, or asphyxia (during the paroxysm). According to Richter's statistics, 88 per cent. of military cases are fatal. In the so-called idiopathic cases the mortality-rate is under 50 per cent. Chronic tetanus gives a less grave prognosis than does acute. There is a direct relation between the duration of the incubation period and the mortality-rate; of 858 recorded cases, when this was less than ten days, the mortality was 76.5 per cent., but rapidly decreased after that period had elapsed.¹ In the newborn recovery is so rare that when it occurs the diagnosis may be called into question.

Treatment.—In traumatic cases the wound must be disinfected and thoroughly cauterized. In order to do this effectively, the agents employed must be brought in contact with every portion of the wound, so that punctured wounds must first be laid open. Excision of the wound, and even amputation, may be advisable in some cases. The fact that the deadly poison is developed at the site of infection gives to the local measures supreme importance in the treatment of tetanus. The application of lipid substances (*e. g.*, Peruvian balsam salve) is found to delay the incubation period (Brockenheimer).

The patient should occupy a secluded room with little light and a carefully regulated temperature. A single nurse will suffice, and all sources of external irritation should be avoided. A nourishing diet is demanded, and rectal feeding must be instituted as soon as it is found that food cannot be administered *per oram*, or the food may be introduced by means of a small stomach-tube or catheter passed through the nostril. Stimulants hypodermically should not be spared when the

¹ *Journal of the Amer. Med. Assoc.*, July 29, 1905.

heart's action becomes quick and feeble. The spasms are best controlled by chloroform-inhalations, and during the intervals the patient should be kept under the influence of morphin, administered subcutaneously. Among other capital remedies are chloral hydrate and Calabar bean. The former may be exhibited in rectal injection (gr. xl—2.59 at a dose), to be repeated at intervals of six to eight hours until the spasm is overcome. The heart, however, must be carefully guarded. Hutchings¹ states that chloretone controls the muscular manifestations successfully. Rarely, potassium bromid, curare, nitrite of amyl, belladonna, and cannabis indica are useful.

Tetanus-antitoxin has been recommended for the cure of the disease, and is prepared in both fluid (antitoxin serum) and dry form. A dried preparation (which does not deteriorate) is also obtainable from Merck and his agents in the form of tubes containing from 4 to 5 grams each; at the time used it may be dissolved in water or in glycerin. Of Tizzoni's dried antitoxin 2.25 grams are to be given at the first dose, and 0.6 gram at subsequent doses. As shown by recent experimentation, antitetanic serum may prevent further invasion, but it cannot cure infection that has already reached the spinal cord and brain. The dose, as recommended by Copley,² should be large (30 c.c. at once, to be repeated at least every six hours until improvement is seen). Stintzing states that 96 cases of tetanus have been treated to date with Behring's serum, with 35 deaths. Behring insists upon giving the serum not later than twenty-six hours after the commencement of the attack. Hoffman³ records recovery in 14 out of 16 cases injected with the serum, intradurally. Magnesium sulphate (2 c.c. of a 25 per cent. solution) may be injected into the spinal canal after the removal of an equal quantity of cerebrospinal fluid.

Prophylactic injections of serum containing at least 500 antitoxic units should be used immediately upon the disinfection of the primary focus. Baccelli advises subcutaneous injections of carbolic acid. The dejecta should also be thoroughly destroyed as the tetanus bacillus has been found in the intestinal tract.

BERI-BERI.

(*Endemic Multiple Neuritis; Kakke; "Weak legs."*)

Definition.—Beri-beri is a specific disease characterized clinically by fever, muscular weakness followed by muscular atrophy, pain, tenderness, paresthesia, gastro-intestinal disturbance, tachycardia, and often general anasarca. It is not certainly contagious.

Historical.—Beri-beri, first recognized by Strabo among the soldiers in the Roman armies while occupying Arabia (24 B. C.), was strangely enough not grouped with the infections until the beginning of the nineteenth century. At this period the subject began to receive the serious attention of Dutch and (a little later) of Anglo-Indian writers, and investigators. As stated by Osler, however, we may date the modern study of the disease from Malcolmson's monograph, published in Madras

¹ *Annals of Surgery*, July, 1909.

² *Brit. Med. Jour.*, Feb. 11, 1899.

³ *International Clinics*, vol. ii., S. 20, p. 17.

PLATE II.

BERI-BERT (Herzog, in *Philippine Journal of Science*).

in 1835. It remained for Sheube and Baelz to point out that the principal morbid lesions are those of a multiple peripheral neuritis.

Distribution.—The disease is endemic in tropical and subtropical countries, but may occur epidemically on shipboard, in prisons, and in armies. Instances of epidemic prevalence in armies are numerous; it was the great scourge of the Roman soldiers in Arabia, of the English troops in India, and of Aguinaldo's armies in the Philippines. Birge has reported an outbreak in which 11 out of 13 of a ship's crew were attacked and Bondurant described the epidemic that occurred at the State Hospital for the Insane at Tuscaloosa, Ala., while J. J. Putnam observed cases among the New England fishermen along the Grand Banks. The principal habitats of endemic neuritis, however, are certain parts of Asia, namely, Japan, China, India, the Malayan Archipelago, the Dutch Colonies, and the Philippines. In all of these countries the cases may multiply under favorable conditions into extensive and devastating epidemics. In England and along the Pacific Coast, among the Japanese and Chinese, it is not uncommon at the seaports.

Pathology.—The essential feature is the changes in the nerves; these are inflammatory and degenerative, involving the medullary sheaths and axis-cylinders. In addition to the peripheral nerves, the pneumogastric and phrenic may be affected. Degeneration in the muscles also occurs, and, not uncommonly, serous effusions.

Etiology.—Although beri-beri is most probably an infectious disease, the specific cause still remains in doubt. Both the bacillus of Hamilton Wright and the coccus of Okata and Kokubo have been shown to bear no causative relation to the disease. The etiological position of the organism discovered by Tscizuki still lacks needed proof. Beri-beri is the result of a protozoan infection (Hewlett and de Korte¹).

A second leading theory as to the nature of beri-beri ascribes the disease to certain articles of diet, more especially rice and fresh fish. The striking diminution in the number of cases in Japan following the introduction of an improved dietary has been adduced in support of the food theory, but it may be here stated that the total number of cases of beri-beri that developed during the Russo-Japanese War (in the Japanese army) is to be placed at a minimum of from 75,000 to 80,000.²

Predisposing Causes.—(a) The principal disposing condition is overcrowding, more particularly when combined with antihygienic surroundings. This fact explains the localized outbreaks in armies, asylums, ships, and the like. (b) Certain climatic factors (*vide* Distribution, *supra*), as heat and humidity, favoring the development of beri-beri; hence natives of tropical countries and imported coolies suffer most. (c) *Age and sex.* More cases occur among males than females, and the decade from 15 to 25 years furnishes a large proportion of the cases.

Symptoms.—The period of *incubation* is not definitely known, but is probably from ten days to one month, or even longer. Prodromata are commonly present; they are *thoracic oppression, epigastric pains, anorexia, headache*, and a slight febrile movement. Rigors rarely occur.

Four clinical varieties are recognized:

1. **Atrophic Form.**—This is characterized by *muscular weakness*, slowly developing, leading to paralysis of the lower limbs and trunk,

¹ *Journal of Tropical Medicine and Hygiene*, October, 1907.

² M. Herzog, *The Philippine Journal of Science*, Feb., 1908.

rarely extending to the arms, head, and neck. Atrophy of the affected muscles quickly ensues, with loss of the deep reflexes. The extensors are more profoundly involved than the flexors. Subjectively, there are *pain* and *tenderness* in the muscles and over the nerve-trunks. The electrical reaction of degeneration is present. Sensory phenomena are constant, such as zones of anesthesia and paresthesia over the affected parts. Slight dropsy may arise. In cases of so-called dry or paralytic form that recover, convalescence is protracted.

2. **The Wet or Dropsical Form.**—The earlier or later development of general anasarca with effusion into the serous sacs, characterizes the wet form. The swelling may be enormous and obscure the wasting, which, however, is less marked than in the atrophic variety. The urine contains no albumin and the edema is firmer than that of nephritis. *Dyspnea*, *cardiac palpitation*, and *tachycardia* are commonly present.

3. **The Acute, Cardiac (Pernicious) Form.**—This serious type may develop acutely either as a primary affection or secondary to a mild form of the complaint. The predominating features are *cardiac palpitation*, *marked dyspnea*, and indications of progressive cardiac failure. A moderate *leukocytosis* is usually present; this was true of my cases. The urine may be scanty or suppressed, while the presence of indican in large amounts may be noted. The *duration* may be brief, not exceeding twenty-four hours, but oftener, perhaps, extending over several weeks.¹

4. **The Mild or Rudimentary Form.**—The initial symptoms may be *catarrhal* in nature, to which are soon added the characteristic features—*pain*, *weakness in the legs*, *paresthesia*, *cardiac palpitation*, and possibly *malleolar edema*. Mild cases may be the forerunners of the types previously described, including acute pernicious beri-beri. The disease is often associated with malaria in the same individual, the result of a blood examination in 4 cases in my care having shown the plasmodium in 3, or 75 per cent.

Diagnosis.—This offers no practical difficulty except in sporadic cases, in which the circumstances under which they arise (*e. g.*, the country or region from which the patient may have come), are unknown. The epidemic form is easily recognized. The grouping of the symptoms of peripheral neuritis with edema, absence of deep reflexes, and threatening cardiac dilatation, leave little room for doubt in any case.

Differential Diagnosis.—In attempting to distinguish other forms of infectious polyneuritis, great stress is to be placed on the absence of the peculiar endemic or epidemic status of beri-beri, of the prominent visceral symptoms, the edema, and of the transudation in the serous sacs. In *alcoholic neuritis* the peculiar history and such characteristics as the prevalence of painful features and trembling are noted; in *diphtheritic multiple neuritis* the *velum palati* is involved.

Course and Prognosis.—The course is interrupted by periods of aggravation and apparent pauses, and on leaving the beri-beric centres, all symptoms may disappear. The *prognosis* is mainly dependent on the intensity of the infection, the presence or absence of associated diseases and the circumstances of the individual patient. The particular variety present in the case in hand influences greatly the outlook, *e. g.*, the cardiac or pernicious form being highly threatening to life. Again, the anatomic seat of the nerves implicated decidedly affects the prognosis.

¹ "Beriberi, with Report of Cases," *The Medical Bulletin*, by the writer.

The *mortality* differs with the seasons, locality and individual epidemics. In Japan the death-rate is only 12.5 per cent., while among the Chinese and Brazilians it is much higher.

Treatment.—1. **Prophylaxis.**—It is most probably a fact that under certain compulsory conditions—individual susceptibility, overcrowding, and a warm, moist climate—the usual hygienic measures will not prevent the outbreak and spreading of this disease. Under these circumstances, removal to a non-contaminated locality alone suffices. The foregoing facts were strikingly confirmed during the recent Russo-Japanese War, when the rigid execution of ordinary sanitary means succeeded in limiting serious outbreaks of typhoid, typhus, scorbutus, and dysentery in the Japanese army, while beri-beri proved a veritable scourge (*vide supra*). Removal of early cases to special hospitals or other suitable places, followed by rigorous disinfection of the houses and rooms in which they have been should be systematically carried out during an epidemic season.

Certain *hygienic measures* of treatment, such as systematic feeding with easily digestible proteids, exposure to fresh air without undue fatigue, should be advised and encouraged. A change to a milder and drier climate is usually efficacious, if practicable. In advanced or well-marked cases rest must be enjoined.

2. **Medicinal Treatment.**—Various methods have been advised, such as the early, free use of the salicylates (Baelz), venesection, and free purgation. While all of these are useful in suitable cases, there is not one that is applicable in every instance. In cases in which serious cardiac dilatation supervenes, venesection for its immediate effect is often effective in saving life. Many of the most distressing symptoms in acute forms (dyspnea, pain, nausea) are benefitted by the use of morphin hypodermatically. The dropsy of the cardiac cases requires rest and saline laxatives, followed by digitalis (M v-x, of the tinct. every third hour). For the so-called cardiac seizures, nitroglycerin or inhalations of the nitrite of amyl are recommended. The atrophied muscles should be treated with electricity and massage, and strychnin with tonics is indicated for the same condition.

MALTA FEVER.

(*Mediterranean Fever; Rock Fever; Undulant Fever.*)

Definition.—A protracted infectious disease, caused by the *micrococcus melitensis*, and characterized clinically by irregular fever, copious sweats, rheumatoid pains, and frequent relapses.

History.—Malta fever was described clinically by Burnett in 1816 as a type of remittent malarial fever, but it was first depicted as a specific disease by Marston in 1859. It is *endemic* in Malta, and from time to time is encountered there, and at other Mediterranean ports, in *epidemic* form. Owing to observations made by Wright on the serum reaction, this disease has been shown to exist in India, Hong Kong, the United States, the West Indies, and Brazil. Kinyoun first suspected the presence of Malta fever on this side of the Atlantic, along the coast

and in the islands of the Gulf of Mexico. Recently, Musser and Sailer¹ recognized the affection in Philadelphia in a soldier who had come from Porto Rico. No essential *pathologic lesions* have been identified with the disease. Hughes² noted an enlargement of the spleen and of the mesenteric glands, and in grave cases, bronchitis and broncho-pneumonia.

Etiology.—Bacteriology.—The *micrococcus melitensis* (Bruce) has been found in certain tissues (the spleen in all fatal cases), and is readily recognized morphologically and by culture. Bruce, in two cases, and Hughes, in four, reproduced the disease in monkeys by the inoculation of pure cultures of the organism. Antihygienic conditions increase morbidity. According to the recent statistics (J. C. Kennedy) there is no special liability according to age.

Modes of Infection.—(a) By the “absorption of urine secreted by cases of Mediterranean fever, and this is one way in which workers in hospitals become infected” (Horrocks). (b) It is extremely probable that human beings are infected by the bites of infected mosquitoes—*Culex pipiens*, *Stegomyia fasciata*. (c) By the absorption of healthy goats’ milk from the alimentary canal (Horrocks).

The incubation-period lasts from a few days to twenty or thirty.

Symptoms.—The disease is of *slow and gradual* development, and the features simulate those of beginning typhoid fever. Headache, bone-ache, anorexia, malaise, and slight fever (often preceded by shiverings); the face may be congested, and epistaxis may be present. The bowels are constipated, and the stools may be blood-streaked. The spleen is always enlarged and frequently painful, particularly on pressure.

Three classes of cases are recognized: (1) A *pernicious* type which is rare and generally fatal (Hughes) and needs no further description here; (2) an *undulant* type, characterized by exacerbations of temperature at pretty regular intervals; (3) a *continued* type, in which a continuous fever persists for weeks and even months.

The *fever* is of a remittent type, with undulating course, and perspirations lasting one, two, or three weeks; this, after an apyrexial period of two or three days, is followed by a relapse, with rigors, higher fever, delirium, and sometimes by diarrhea and increased prostration.

The *relapse* frequently lasts from five to six weeks, and then, after a week or two, a second relapse may ensue; symptoms somewhat similar to the first—rigors, intermittent form of fever, extreme prostration, and general rheumatoid symptoms. The latter may be so well marked as to prohibit muscular movements of any kind. The case now either terminates in recovery, or, after the lapse of one or even two months, there may be a repetition of the whole symptom-complex. In *grave cases* the temperature is continuous, and death may occur in hyperpyrexia (Hughes). The temperature range is often markedly irregular, hence its comparative uselessness, as claimed by Craig, from a diagnostic point of view. A polynuclear leukocytosis is present in Malta fever. Certain *complications*, as touches of pleurisy and pneumonia, rarely appear.

Diagnosis.—From the use of pure cultures of the special organism in the blood of Malta fever patients gives a typical agglutination. Thus the affection is with ease and certainty distinguished from *typhoid fever* and erratic forms of *malaria*. In no other manner can it be discriminated

¹ *Phila. Med. Jour.*, Dec. 31, 1898.

² *Annales de l'Institut Pasteur.*

from typhoid fever in the earlier stages. The presence or absence of the Widal reaction will assist in the differentiation. If *malaria* is suspected, a microscopic examination of the blood should be made. Many cases present hacking cough and physical signs of lung congestion, or even consolidation, and, as a consequence, are looked upon as instances of *incipient tuberculosis*. The serum test will remove all doubt. Malta fever not infrequently, in its mode of onset and the symptoms present during the first few days, resembles *lobar pneumonia* (Craig). The absence of rusty sputum, stabbing chest pains, and the milder character of the cases, however, are an aid in excluding pneumonia. The polyarthritides with fever has led to confusion with *acute articular rheumatism*. *Pyemia* must also be excluded.

Duration and Prognosis.—Soldiers show an average stay in the hospital of ninety days (Bruce); obstinate cases, however, may last six months. Most cases pursue a chronic course. The death-rate is low—about 2 per cent. Death is generally due to hyperpyrexia.

Treatment.—This should be sustentative or supportive, in view of the uncertain, protracted course. Nourishing liquids and, usually, stimulants are required. Dalton allows solids, such as eggs, rice, and bread, in addition to 2 to 3 quarts of milk. The bowels should be moved daily. Fever is to be combated by the application of cold (cold bath, wet pack, or sponging). There are no special remedies. Bassett-Smith¹ reports two series of cases treated with vaccine prepared from cultures of *Micrococcus melitensis*, freshly isolated from the spleen during life, with gratifying results. Tonics, coupled with a change of climate, favor convalescence. Hematinics are especially indicated during this period to overcome the well-marked secondary anemia.

PROBABLE INFECTIOUS DISEASES.

MUSCULAR RHEUMATISM.

(*Myalgia*.)

Definition.—A common, painful disease of the muscles and of the structures to which they are attached (fasciæ and periosteum), probably due to an attenuated form of the virus of acute articular rheumatism. Leube contends—and very properly, I think—that muscular rheumatism is a general disease with local symptoms. The latter may be seated in different parts of the body, and in this way give rise to a number of leading sub-varieties, and it may either accompany acute and chronic rheumatism or it may be experienced as an independent disease. I have also met with several instances in which it followed joint-rheumatism, and Leube has seen it precede the latter. Certain authors believe that the affection is a neuralgia of the sensory nerves of the muscles.

Pathology.—In fatal cases (these are exceedingly rare) the affected muscles show a swelling of the fibers and more or less granular change. In long-standing cases there is an atrophy of the muscles, due to trophic disturbance. Strauss describes circumscribed nodules in the muscles.

¹ *Journal of Tropical Medicine and Hygiene*, May 15, 1907.

The changes are essentially those of myositis. In the acute form there is often an extensive round-cell infiltration of the connective tissue, with swelling and partial degeneration of the muscular fibers and the formation in them of vacuoles. In the chronic form there is a proliferation of the interfascicular connective tissue.

Etiology.—Among the disposing influences that are most important in the causation of the affection are—(1) The *rheumatic diathesis* (appropriate soil); (2) *Heredity*; (3) *Exposure* to cold, damp, and strong air-currents, especially after heavy exercise or during free perspiration; (4) *Sex*, owing to the more frequent exposure of men while following their occupations; (5) *Age*. It is met with at all ages, but acute and subacute forms most frequently occur among children and young adults, while the chronic form most frequently affects elderly persons; (6) *Previous attacks* increase the susceptibility to the disease. (7) *Lumbago* may be reflex in character, due to hemorrhoids, enlarged prostate, and intestinal irritation.

Symptoms.—In the majority of instances the clinical symptoms are local. Out of 200 cases Leube found *fever* in about one-third, the temperature rarely exceeding 102° F. (38.8° C.) for two days in duration. In one-sixth of Leube's cases there was a cardiac murmur that disappeared under treatment in one-half of this number. *Pain*, which is sometimes sharp, lancinating, and paroxysmal, while in other cases deeply seated, dull, and constant, is troublesome. It is aggravated at night by contraction of the affected muscles, by weather-changes, and by pressure. In long-continued cases pressure with the broad side of the hand usually affords relief. The *duration* ranges from a few hours to several days or longer. The rheumatic nodules are common in the shoulder- and calf-muscles. The cases in which the symptoms tend to persist or recur with changes in the weather may be termed *chronic*.

Leading Clinical Varieties.—(1) *Lumbago (Myalgia Lumbalis)*.—This is the most common form, and may be taken as the type of the myalgias. The *onset* is sudden, sometimes intensely so, and the lumbar muscles are exceedingly painful and sensitive. *Motion*, such as stooping or turning the body or rising from the sitting position, causes intense exacerbations of pain. The affection occurs most frequently in laboring-men, its course being brief, as a rule, and recurrences frequent. Erben, from a study of 200 cases of lumbago, finds that the trouble is principally an affection of the lumbar vertebræ, or a neuralgia of the cutaneous nerves.

(2) *Pleurodynia*.—This term implies involvement of the intercostal muscles, and less frequently of the pectorals and the serratus magnus. It is unilateral, and oftener affects the left than the right side, and causes untold suffering, since it is constantly aggravated by the normal respiratory excursions. The pain is also intensified by pressure, reaching, etc., and by movement of the trunk, sneezing, and coughing. Similar symptoms may be occasioned by *traumatism* in which the fibers of the thoracic muscles are lacerated, and there is also great danger of confounding pleurodynia with *costal periostitis* and with *pleurisy*.

(3) *Torticollis (Myalgia Cervicalis)*.—Here the muscles, some or all, on one side of the neck, and at times the throat, are implicated. The head is held toward the affected side, so as to relax the group of muscles involved, and on attempting to turn it the patient rotates his entire body in a pivot-like manner. The complaint is frequent in young persons.

(4) **Cephalodynia.**—By this term is meant rheumatism of the head-muscles of the scalp and fasciæ. It may be either *general* or *local*, being sometimes limited to the frontal, temporal, or occipital muscles. The *pain* is severe and greatly increased on motion of the scalp.

(5) Other terms descriptive of localized forms of muscular rheumatism are employed: (a) *Omodynia* (myalgia of the deltoid); (b) *Dorsodynia* (involvement of the muscles of the upper part of the back, etc.); (c) *Abdominal rheumatism* (myalgia of the muscles of the abdomen); (d) *Rheumatic myositis* of the extremities.

Diagnosis.—This is assured by the etiologic influences and the presence of pain, which is greatly increased by muscular contraction. The presence of fever does not exclude the affection. It differs from *neuralgia* in that there are no painful points, and in that firm pressure with the broad hand often affords relief. On the other hand, in *gonorrheal rheumatism* the plantar fasciæ are commonly involved and the patient complains of pain in the head. *Dermato-myositis* must not be confounded with muscular rheumatism. Unverricht first distinguished the former from the latter, showing that there are present pain and swelling of the muscles, as in muscular rheumatism, but additionally redness (erythema) and hyperesthesia of the skin, while the joints usually escape. Of general symptoms, the chief are fever and physical prostration. The spleen is enlarged, and angina and hemorrhages have been noted. The disease is obviously infectious, probably septic in nature, and may rarely prove fatal. Dermatomyositis, unlike muscular rheumatism, is more common among women, especially servants, than men. *Abdominal rheumatism* has been mistaken for appendicitis.

The **prognosis** is good, the disease never endangering life, though a person may be incapacitated for work by muscular rheumatism.

Treatment.—Severe and acute forms demand the use of opiates internally and anodyne and hot applications externally. When cases are seen early, morphin, administered hypodermically, may serve to relieve the pain and cut short the disease. In acute cases the salicylates and other antirheumatic remedies are to be employed. Hot fomentations give comfort, and the Turkish bath may end the attack if it can be used sufficiently early. The hot-water bag, sponging with water as hot as can be borne, or dry heat in the form of bags filled with heated salt or heated hops, will all do good service. For the dull pain which is so distressing in some cases of torticollis the affected muscles may be covered with flannel, over which a warmed flatiron may be passed for a few minutes. This is an efficient expedient. For lumbago acupuncture is highly commended. Needles of from three to four inches (7.5–10 cm.) in length (ordinary bonnet-needles, sterilized, will do) are thrust into the lumbar muscles at the seat of the pain and withdrawn after five or ten minutes (Osler). Schmidt recommends local injection of 5 or 10 c.c. of physiologic salt solution for the relief of pain. Blisters have been recommended, but I have tried them without beneficial effects. In sub-acute and obstinate cases I have recently obtained good results from the use of a 20 per cent. ointment of salicylic acid freely rubbed into the skin. Active friction with anodyne and stimulating liniments (the latter when pain is not great) is worthy of trial. Massage and electricity (constant current) are sometimes efficient, and in chronic cases potassium iodid, guaiacum, and arsenic (the latter in small doses) should be tried.

The same measures of prophylaxis are to be adopted as in chronic rheumatism, and the condition of the general health must also be looked to, every endeavor being made to maintain the proper quality of blood and perfect nutrition.

CHRONIC ARTICULAR RHEUMATISM.

Definition.—An affection of the articular structures which develops slowly and gradually and may have the same etiology as the preceding forms. Rarely it is a sequence of acute or subacute attacks.

Pathology.—The joints, as a rule, do not show pronounced gross lesions, there being some degree of synovial injection and also some, though not much, effusion. Inflammatory thickening of the articular and periarticular structures (capsule, ligaments, sheaths of the tendons, etc.) with contraction, is noted, and is a change which deforms and stiffens some joints to a certain extent. Superficial erosions of the cartilages may also be witnessed, and muscular atrophy supervenes. The probable causes of these important changes have been pointed out in connection with the latter disease. When the shoulder-joint is the seat of chronic inflammation, this muscular atrophy (affecting chiefly the deltoid) reaches its highest degree of development.

Etiology.—(a) *Age* predisposes to the affection. Though it may appear at any age, the greatest number of cases is furnished by the years from forty to sixty. (b) *Sex* exerts a slight influence, the disease being observed most frequently among females. (c) *External agencies*, as poverty and occupations which entail exposure to cold and dampness. (d) *Heredity* may operate to favor its development.

Symptoms.—The involved joints may not present any visible evidences of disease, and perhaps the most prominent local symptom is *pain*, increased often at night as well as by approaching cold or damp weather. Both the larger and smaller joints are involved, though the former to a greater degree, and yet, though usually multiple, the disease may be limited to one joint (knee, hip, shoulder, etc.). The joints are somewhat *swollen*, as a rule, at times slightly reddened, tender upon pressure, and their mobility is generally restricted. Pain and *stiffness* are most marked in the morning hours (after rest), and often largely disappear with each returning evening (after use). All the local symptoms are subject to exacerbations and remissions. A peculiar *crepitation* may be elicited on applying the hand over the affected joints during motion, and eventually ankylosis, with some degree (usually slight) of distortion of the joints, may occur.

The *general features* are usually conspicuous by their absence. No fever is present, and, in most instances, there is no serious impairment of the general health. On the other hand, as the result of constant suffering, a wretched general condition with marked anemia and debility may finally be reached, such patients often passing sleepless nights and suffering severely from dyspepsia. Chronic endocarditis may develop along with the chronic articular changes—a not uncommon association, though frequently the history of a previous attack of acute rheumatism is also obtainable, to which the endocarditis may be attributed (for the differential diagnosis of this disease *vide* Arthritis Deformans).

Prognosis.—Full recovery is, with but few exceptions, out of the question. A cure may rarely be effected if the case come under appro-

appropriate treatment in the incipient stage. The disease, however, rarely shortens the duration of life, though it may do so by interfering with the nutritive processes, the latter effect resulting from loss of sleep (due to pain) and inability to take active exercise.

Treatment.—(a) **The local measures** hold first place. The affected joints should be enveloped in flannel at all times, and underneath the latter may be applied cold cloths, and the whole covered with oiled silk. On the other hand, sponging the joints frequently with hot water relieves the pain and stiffness. Bier, Reed, and others, employed a hot-air treatment with good effects. Blisters are efficacious in removing effusions. In the absence of synovial effusion the thermo-cautery is to be preferred to blisters, and for the swelling and stiffness massage with passive movement affords excellent results. Massage is also valuable when atrophy of the adjacent muscles exists; and in these so-called “rheumatic paralyses” electricity is an important help. Iodin and stimulating liniments are more or less serviceable.

(b) **Hygienic Measures.**—The diet should be abundant and nourishing; it may embrace milk, eggs, the lighter forms of meat, fats, farinaceous articles, and cruciferous vegetables; wines and alcohol may be permitted. Dietetic abuses, however, tend to aggravate the arthritic condition. The patient should adopt and continue moderately active exercise until compelled to omit it on account of the advancing joint-lesions. Cold spongings of the skin-surface, followed by active friction, have a good effect in that they lessen cutaneous sensitiveness.

(c) **Internal remedies** do not control the morbid process directly, although arsenic, iodine, potassium iodide, guaiacol, and other agents are much used for this purpose, but their effects are usually limited, and never brilliant. It should be our aim to maintain the general health at a maximum level by the employment not only of the sanitary means before alluded to, but also by tonics (iron, quinine, strychnine, etc.). A course of cod-liver oil is the most serviceable form of internal medication.

(d) **Hydrotherapy** is an important adjuvant to the treatment.

The thermal springs whose waters are alkaline or contain sulphur, and of which the hot springs of Arkansas and Virginia, and the Richfield Springs, New York, furnish good examples, have been strongly advocated, and sometimes prove curative in their effects. I have seen excellent results from the methodic use of hot-water baths at a constant temperature (100° to 105° F.—37.7° to 40.5° C.), combined with passive motion and careful manipulation of the affected parts. Every precaution must be used to avoid exposure to cold or draft during and after the baths, which should not be prolonged beyond ten minutes.

MOUNTAIN FEVER.

(*Mountain Sickness*).

The term “mountain fever” should be regarded as applicable only to a condition produced by the action of a rarefied air upon the organic functions. There is no definite *pathology*. Aron’s investigations show that the intake of oxygen is diminished at high altitude.

The **symptoms** are a much-quickened pulse, urgent dyspnea, headache, vertigo, and at times nausea and vomiting. There is a subfebrile

movement, the temperature touching 100° F. (37.7° C.) or even 101° F. (38.3° C.). Thirst is present and the appetite is lost. Malaise and a sense of exhaustion on attempting exertion are experienced. Hemoptysis has been noted, but rarely. The effect upon the human economy of high altitude varies with the extent of the differences in individual reserve nerve-force. Rest and acclimatization will almost invariably restore healthy function. Oxygen inhalations are advised (Aron).

The "mountain fever" of the older writers is almost universally conceded at the present day to be typhoid fever modified by the effects of extreme altitude.

ROCKY MOUNTAIN SPOTTED FEVER.

Historic Note.—This disease has been known in the valley of the Bitter Root River, in Western Montana, during the past twenty years. Rock Creek and Bonito, nearly twenty miles distant from Bitter Root Valley, have furnished a limited number of cases.

Mountain spotted fever has also appeared in the valleys of streams situated in the mountainous sections of Northwestern Nevada, Southern and Western Idaho, and in Northern Wyoming.

Predisposing Causes.—*Climate.*—Mountain spotted fever has not been observed south of 40° or north of 47° N. lat., and epidemics are most prevalent at elevations ranging from 3000 to 4000 feet.

Season.—The disease prevails exclusively during spring and early summer months.

Occupation, Age, and Sex.—Persons who are compelled to be in the open air and among the woodlands and farming districts are most likely to become infected.

In Anderson's¹ analysis of 121 reported cases, 76 were males and 45 females. Most of the cases occurred between the fifteenth and fiftieth years of age.

Parasitic Origin.—A series of investigations, conducted by Anderson, showed that the *Pyroplasma hominis*, a parasite closely allied to the *Pyrosoma bigeminum* (known to cause Texas fever in cattle) and found within the body of the red blood-corpuscles, is the infecting parasite. He further believes that the disease is transmitted to man through the bite of ticks (*Dermacentor reticulatus*) common to infected districts.

Incubation.—The period of incubation varies from three to ten days, seven days being the rule. During three or four days of this period the patient experiences slight chilly sensations, malaise, and nausea.

Clinical History.—The disease is ushered in by a distinct chill, which is followed by a rapid and continuous elevation in the temperature, with slight morning remissions, until the tenth to the twelfth day, and in fatal cases it reaches 104° to 106° F. In favorable cases the temperature reaches the maximum from the eighth to the tenth day, after which there is a gradual decline to the normal by the fourteenth day.

Following the chill the patient experiences pain in the back and loins, soreness of the muscles, the limbs are moved with difficulty, and there is always slight, and at times severe, nose-bleed after the first week of fever;

¹ *Hygienic Laboratory Bulletin*, No. 14. "Public Health and Marine-Hospital Service of the United States," p. 8.

the tongue is heavily coated at the center and base, while its edges and tip are red; nausea and vomiting are common, and persistent constipation is the rule. The conjunctivæ are at first congested and later assume a yellowish tinge; the urine is febrile in character, being diminished in quantity and containing a moderate amount of albumin and also renal casts; the respirations range from 25 to 60 per minute, and it is not uncommon for the patient to develop bronchitis from the third to the sixth day of fever; the liver and spleen are enlarged.

The pulse is weak and rapid, being out of proportion to the temperature. The mind is, as a rule, clear even in the severer forms of the disease, until approaching death.

Eruption.—The eruption is rather characteristic; it appears on the third to the fourth day, on the wrists and ankles, from which points it spreads to the arms, legs, forehead, back, chest, and, lastly, to the abdomen.

The spots are at first bright-red maculæ, varying from the size of a pin's point to that of a pea. In the severer forms of the disease these maculæ become dark and later assume a purplish tinge. They begin to fade at about the sixth day, and lose their petechial character with the decline of the fever at or about the fourteenth day.

Blood.—During the course of the disease the red blood-cells show evidence of destruction, and the white cells may be slightly increased in number. The hemoglobin may gradually fall to 50 per cent.

Diagnosis.—Mountain spotted fever is to be differentiated from *cerebro-spinal meningitis*, *peliosis rheumatica*, *malaria*, *typhoid fever*, *mountain fever*, and *purpura hemorrhagica*. The eruption is very similar to that of *typhus fever*, but the spleen is less habitually enlarged in the latter disease, which also runs a shorter course with a more abrupt onset and termination of the fever.

Prognosis.—Of 121 cases occurring in the Bitter Root Valley district, 84 were fatal (Anderson). In other districts the rate of mortality may reach 90 per cent. Death usually occurs between the fourteenth and eighteenth days of the disease, and may result from complications, among which pneumonia deserves special mention.

Treatment.—The treatment is ordered to meet the indications presented by each individual case. L. B. Wilson and Anderson have suggested the use of quinin hypodermically. Morphin, in the form of Dover's powders, is usually required to relieve the intense pain and soreness. Hot sponge-baths are of value in relieving the temperature. The *diet* should consist of milk, broths, soft-boiled eggs, and soft toast.

WEIL'S DISEASE.

(*Acute Febrile Jaundice; Fiedler's Disease.*)

Definition.—An acute febrile disease, probably specific in origin, and characterized by jaundice, remittent fever, and muscular pains. It usually runs a definite course and terminates by lysis.

Pathology.—During the comparatively recent studies of the post-mortem lesions occurring in this disease very little has been noted. The liver and spleen are sometimes the seat of an active hyperemia, and occasionally some gastro-intestinal irritation is present. The cortical substance of the kidneys is swollen and mottled, and the epithelium of the tubules and glomeruli shows cloudy swelling.

Etiology.—The special organism of the disease is unknown ; indeed, it may be an acute febrile jaundice of varied etiology. Jaeger claims that it is due to infection by the *bacillus proteus fluorescens*. Certain French authorities consider the disease a ptomain poisoning.

Predisposing Causes.—Among these may be mentioned the following :

(a) *Age.*—The age of the patient usually varies from twenty to forty years. A. Holz records a case in a woman fifty-one years old.

(b) *Occupation.*—*Butchers* are most commonly affected. Workers in ditches and sewers or those exposed to foul water are particularly prone to infection.

(c) *Sex and Season.*—Most of the recorded cases occurred in males and during the summer months.

(d) *Locality.*—The cases have appeared in groups, in both rural and urban localities.

Symptoms.—The disease is usually ushered in by a *chill*, followed by *fever*, *headache*, and *pain* in the muscles, joints, and epigastrium. *Jaundice* usually appears on the second day, and may either be slight or very intense ; if it be due to obstruction, the stools are gray-colored, showing the absence of bile. The fever is of the remittent type, running from ten to fourteen days and terminating by lysis. Nausea, vomiting, and diarrhea may rarely occur. The *liver* and *spleen* are often enlarged, the latter being tender on pressure. The *urine* is febrile, high-colored, and often shows the presence of albumin, with tube-casts, and sometimes blood (hemoglobinuria). In grave (but rare) cases *cerebral symptoms*, such as delirium, convulsions, and coma, may occur and prove fatal.

The **diagnosis** rests on the acute onset, fever, pains in the muscles, joints, and epigastrium, nephritis, and icterus. *Schlammfieber*, which prevailed mainly among young persons who had worked in the recently flooded districts near Breslau during the summer of 1891, and assumed epidemic proportions, has not been satisfactorily classified. Müller shows its resemblance in many respects to Weil's disease, which may occur at times without jaundice (?).

Prognosis.—The prognosis, both as to life and recovery, is good. W. E. Hughes, notwithstanding, records two cases that proved fatal within forty-eight hours of the onset.

The **treatment** is purely symptomatic. The *diet* should be fluid, such as milk, broths, and the like. Hydrotherapy is indicated in the more toxic cases. The muscular pains may be relieved by warm stupes and fomentations.

FEBRICULA.

(Simple Continued Fever ; Ephemeral Fever.)

Definition.—A brief febrile attack, unattended with definite local lesions, and of varied, often indeterminate etiology. A true ephemeral fever is one that lasts about twenty-four hours, while the term simple continued fever or febricula is given to cases lasting a longer period.

The cases are diversified with reference to their **etiology** and clinical relations, but may be roughly grouped under several heads :

(a) A large group of cases in which a *gastro-intestinal disturbance* is the only assignable cause. The latter may be due to cold or more often to errors in diet (particularly the use of tainted food-stuffs), accompanied

by absorption of ptomaines, or it may assume the form of gastro-intestinal catarrh met with in young children.

(b) Undeveloped or abortive forms of the *infectious diseases* (typhoid, influenza, rheumatism). These affections, particularly during times of epidemic prevalence, may run a brief course without manifesting any of their distinctive characters. This is particularly true of the abortive types of typhoid, and other acute infections. Again, diseases that ordinarily manifest a characteristic eruption (*e. g.*, scarlet fever, measles, erysipelas) may run their course without doing so, or the eruption may escape observation.

(c) It may follow *exposure* to the summer sun or *excessive heat* (?), or *exhaustion of the nervous system*.

(d) It is not infrequently the result of a slight and unnoticed *localized inflammation* (tonsillitis, bronchitis, lymphadenitis, etc.).

(e) The *inhalation of sewer-gas or other noxious vapors* (such as emanations from decomposing organic matter) may produce an aberrant form of the fever (*vide* Septicemia).

Symptoms.—It is to be remembered at the outset that a single symptom, peculiar to all cases, is the *fever*. The *onset* is generally sudden, and especially in ephemeral fever, but it may be gradual; if sudden, there is rarely either a chill or vomiting, while in neurotic children a convulsion may occur. The temperature ascends quickly to 102°–103° F. (39.4° C.) or over, pursues the continued type, and at the end of one, two, or more days subsides abruptly by crisis. There are accompanying symptoms, many of which are due to the fever, such as headache, hebetude, mild delirium, flushed countenance, a full, rapid pulse, anorexia, constipation, scanty, high-colored urine, and, not rarely, herpes labialis. Defervescence may be attended with critical sweats, diarrhea, or a copious flow of urine. *Special types* (*e. g.*, cerebral, gastric, gastro-intestinal) may be observed, due to the predominance of the symptoms presented by individual organs or systems.

In another class of cases the access of simple fever may be less sudden, the maximum level attained being somewhat lower and the attending phenomena less acute and pronounced. Da Costa¹ has described cases belonging to this category. The *course* is more protracted, though rarely exceeding a week or ten days, and the defervescence is not so abrupt. So-called *thermic fever* is at the present writing believed by Guitéras, who first described it, to be due to a special, though as yet unknown, organism.

The **diagnosis** necessitates the exclusion of other acute fevers. The affections from which it is most difficult to distinguish febricula are *typhoid fever*, *remittent fever*, *scarlet fever*, *incipient tuberculosis*, *larval pneumonia*, and *meningitis* (in children). In febricula, however, there is an absence of local manifestations and of physical signs pointing to consolidation of the lungs; characteristic skin-eruptions are also absent. Tyson points out that in cases in which there is splenic enlargement (rare) the resemblance to typhoid is close, and the diagnosis may have to remain in doubt until settled by the Widal test or by time. The cases must also be discriminated from the fever which sometimes attends chlorosis and certain nervous disorders.

¹ *Transactions of the Association of American Physicians*, vol. xi., 1896.

The **prognosis** is good.

Treatment.—Few cases require treatment other than rest in bed and liquid nourishment for several days. Cooling drafts internally, and mild forms of hydrotherapy (spongings, ice-caps) externally, are indicated. If traceable to gastro-intestinal disturbance, a laxative usually proves beneficial and effective. It should be followed by intestinal antiseptics. Unless it is clear that the given case is non-infectious and non-contagious, isolation of the patient should be ensured.

MILK-SICKNESS.

Definition.—A peculiar infectious disease, occurring both in man and in the lower animals, when it is known as “trembles.” The disease is unknown east of the Alleghany Mountains, but throughout many of the Western and South-western States it formerly prevailed very extensively, with fatal effect. It has, however, been almost exterminated as the result of denudation of the forests and the advancing cultivation of the virgin soil. It still prevails in parts of North Carolina (Osler), and until very recent times has been seen in certain parts of Illinois.

No peculiar pathologic lesions have been described.

Etiology.—It is believed to be due to a special poison derived from the earth, but as yet we are ignorant of its exact nature. Phillips claims to have found a spirillum in the blood.

Modes of Infection.—The disease attacks cattle most frequently (especially unweaned calves), horses, sheep, goats, and less often many undomesticated animals; wherever trembles prevails among cattle, milk-sickness is met with in man. It is thought that the poison is communicated to man in the milk, butter, and cheese, or in the flesh of infected animals.

Among disposing factors are the *seasons*, the disease being most frequent in the late summer and autumn. It is most common in adult life.

Symptoms.—The period of *incubation* may be short or long in duration, and *prodromata*, such as headache, anorexia, languor, and oncoming fatigue, may be noted. These symptoms increase in severity, and are soon eclipsed by the more characteristic features—nausea and vomiting, a hot pain in the stomach, and a peculiar fetor of the breath. There is an unquenchable thirst, a swollen, tremulous tongue, and absolute constipation. Fever is present, but it is slight, and the surface-temperature is often below the normal. The nervous symptoms include restlessness, merging into mental dulness with marked indifference, and the latter condition passing in grave cases into a stupor that may deepen into actual coma. Convulsions may arise or the patient may drop into a fatal typhoid state.

The **diagnosis** rests chiefly upon the history (particularly upon the coexistence of “trembles” in cattle) and the exclusion of other acute intoxications.

The **prognosis** is generally favorable, though a fatal termination due to asthenia may occur within a few days of the time of the onset.

Treatment.—*Prophylaxis* consists in the avoidance of those foods that act as bearers of the disease. Apart from the use of supporting measures (appropriate diet and stimulants), we can attend only to the symptomatic indications. Medicated enemata should not be omitted.

MILIARY FEVER.

(Sweating Sickness.)

Definition.—An infectious disease, characterized by copious sweats and a vesicular (miliary) eruption. In certain countries it has prevailed epidemically (France, England, Italy, Germany), and in 1887 a severe epidemic occurred in France. Schaffer¹ reports the occurrence of a recent epidemic in an Austrian province in the spring of 1893, lasting for nearly three months. Out of 5079 persons (the total population of the district), 159 suffered, as follows: 17 men, 14 women, and 128 children. At the present day it seems to be met with only in Picardy, in a few other French provinces, and throughout a limited area in Italy.

Neither have definite *pathologic lesions* nor the *specific exciting cause* been found. Among *predisposing influences* the following have been noted: (a) Most epidemics occur in spring and summer; (b) It is more common among women than men, and most frequent during the middle period of life. A large percentage of the entire population of an invaded district (usually limited in area) is attacked.

The **symptoms** that characterize miliary fever are *fever* with its usual accompaniments, irritation of the skin, epigastric oppression, copious and persistent sweating, followed, on the third or fourth day of the disease, by an *eruption* (due to profuse sweatings) of miliary vesicles. A. Weischelbaum² has shown by serial sections through sudaminae that the fluid in the latter is not due to retained secretions in the sweat glands, but is always of an inflammatory nature.

The vesicles burst, and within forty-eight hours scaly desquamation is generally completed. In severe types the nervous phenomena (delirium, etc.) are grave in character; hemorrhages may occur, and at times fatal collapse may follow. *Relapses* are not uncommon.

The **prognosis** is affected largely by the character of the epidemic, the average death-rate being 8 or 9 per cent.

Quinin has met with almost universal favor as a remedy, but the expectant plan of **treatment** is the most appropriate, the indications being fulfilled as they arise. The sweating may demand atropin.

FOOT-AND-MOUTH DISEASE.

(Epidemic Stomatitis; Aphthous Fever.)

Definition.—An acute infection of certain lower animals (cattle, sheep, pigs, goats), caused by a micro-organism as yet undiscovered, although Klein has described a micrococcus. It is characterized by fever, by the appearance of vesicles and ulcers in the mucosa of the mouth, in the furrows about the feet and on the udder, and by the rapid development of asthenia and marked emaciation. Though a disease of mild character, its territorial range is so vast as to entail untold loss to European countries. Young animals or sucklings perish in great numbers on account of the deteriorated quality of the milk, which assumes a yellowish-white appearance and has a bitter, nauseating taste.

During epidemics of foot-and-mouth disease the poison may be trans-

¹ Wiener med. Blätter, 1893, No. 32.

² Zeit. f. Klin. Med., 1907, lxii, 21.

ferred to man, in whom the disease is known as *epidemic stomatitis*, the poison generally being transferred by means of milk. Boiling the latter destroys the virus, but rarely the infection may be transmitted through butter and cheese made from the milk of infected cattle. Communication by inoculation (while milking) may also occur. The disease does not seem to be transmissible through the meat of diseased animals.¹ In America a few instances only of transference from animals to man are recorded.

Symptoms.—The *incubation-period* lasts from three to five days. A rigor may mark the onset or merely slight shiverings, followed by fever and malaise, and soon vesicles, such as are described under Aphthous Stomatitis, appear upon the tongue and inner surface of the lips. The mouth is hot, the mucosa reddened and swollen, and salivation is present. A form of miliary eruption that may become pustular may also appear on the skin-surface, and particularly on the fingers and hands. Hemorrhages have been observed in severe epidemics.

The **diagnosis** is made with ease if the disease be prevailing at the same time among lower animals. The peculiar coincidence of the eruption in the mouth and extremities, sparing the rest of the body, has not been noticed in any other eruptive disease (Whittaker).

Course and Prognosis.—The course is mild and ends in about one week, the disease being very rarely fatal.

Treatment.—*Prophylaxis* requires the use of milk from healthy animals (cows or goats), together with measures looking to the care of the stables and isolation of diseased cattle. A reliable method of immunization against foot-and-mouth disease has not as yet been discovered.² For *treatment* the reader is referred to the article on Aphthous Stomatitis.

GLANDULAR FEVER.

Definition.—By this term is meant an acute infectious disease of children, characterized by adenitis affecting the lymph-glands of the neck, especially the anterior cervical.

History.—A detailed description of glandular fever was first given by E. Pfeiffer, in 1889, under the name of *Drüsenfieber*, but it had probably been previously described by Filatow, of Moscow. Donkin, Fischer and Dawson Williams, in England, and J. Park West have given excellent descriptions of the disease.

Pathology.—The anterior cervical lymphatic glands are involved first, and it is "probable that the infection finds its point of entrance through either the tonsils or the pharyngeal mucous membrane" (Williams). The adenitis may also affect the inguinal and axillary glands.

Etiology.—The special micro-organism of the disease is unknown, although Burns has isolated the staphylococcus aureus. The complaint occurs usually in the form of house-epidemics. West, of Ohio, however, has described the most widespread epidemic hitherto recorded. There were 96 cases in 43 families, and rarely did a child exposed to the infec-

¹ Zuell's translation of Friedberger and Fröhner's *Pathology and Therapeutics of the Domestic Animals*.

² Siegel, "Experiments in Immunization against the Poison of Bites and Scratches." Quoted in the *Philadelphia Med. Jour.*, January 28, 1899.

tion escape. The disease usually occurs during childhood; the ages of West's cases ranging from seven months to thirteen years. A. E. Rousell has reported four cases, one occurring in an adult. Most cases occur between the months of October and May, inclusive. According to Hand, the weight of clinical evidence tends to variation in the etiology in different cases (*e. g.*, it is often one of the protean manifestations of influenza).

The incubation-period lasts usually from five to eight days.

Symptoms.—The *onset* is *sudden*. The child holds the neck stiffly, since movement causes pain; there are anorexia, nausea, and less commonly vomiting, the bowels are constipated, and often there is abdominal pain. The child may complain of pain and swelling; an examination of the pharynx may show some chronic enlargement of the tonsils, and in some cases injection of the pharyngeal mucosa, actual pharyngitis being rare. The temperature oscillates from 101° to 103° F. (38.3°–39.4° C.). Nervous symptoms (delirium, hebetude) are rarely observed.

The *glandular enlargement* becomes obvious on the second or third day, and in most cases is observed first on the left side, then, after a few days, on the other side of the neck also. The glands vary in size from a bean to a hen's egg, and are painful on palpation. They rarely suppurate. Other groups of glands (axillary, inguinal) may be successively involved. Cough and dyspnea may point to involvement of the bronchial and tracheal glands. The mesenteric glands were enlarged in 38.5 per cent. of West's cases. Splenic enlargement occurs in 50 per cent. of the cases, while the liver is increased in size in almost all cases. There is a leukocytosis varying from 18,000 to 25,000. The average *duration* is sixteen days (West). Among *complications* may be mentioned hemorrhagic nephritis, bronchitis, and otitis media.

Diagnosis.—The recognition of glandular fever embraces the exclusion of such affections as *tonsillitis*, *pharyngitis*, and *influenza*, in the course of which adenitis might arise. Griffith¹ has reported cases resembling glandular fever in which influenza was probably the sole disease present.

Prognosis.—Recovery is the rule.

Treatment.—The course of the disease is probably uninfluenced by treatment. Locally, cold compresses and fomentations are useful. Internally, West advises castor-oil in the early stage, followed by minute doses of calomel (gr. $\frac{1}{2}$ to $\frac{1}{10}$) twice or thrice a day.

PART II.

ANIMAL PARASITIC DISEASES.

PARASITES OF MAN.

The human species furnishes a habitat for many varieties of parasites. Protozoa, including the Amebas and Infusoria, Plathelminthes, Nematodes, Leeches, Arachnoids, and Insects. Some infest the body surface, while others find their locus in the intestines, bone marrow, vascular system, muscles, brain, genital apparatus, or solid viscera.

CHRONIC AMEBIC DYSENTERY.

Etiology.—This disease is caused by the *amœba dysenteriae* (Councilman and Lafleur) or the *entamoeba histolytica* (*amœba coli*). The *amœba dysenteriae* is a unicellular, motile organism, in size 3 to 7 times the diameter of a red blood-corpuscle (15 to 30 micromillimeters). Its protoplasm consists of two zones—an outer colorless (ectosarc) and an inner granular zone (endosarc), with a visible nucleus and one or more vacuoles. This micro-organism was first described by Lambl (1859), but it remained for Lösch, and especially Kartulis, to show its close association with dysentery. The ameba (*amœba coli mitis*) is occasionally found in healthy individuals, and also in other bowel affections than dysentery (mucous enteritis, simple diarrhea, proctitis due to engorgement), and two species are recognized—a virulent *entamoeba histolytica* and a benign form, *entamoeba coli*. Walker's studies, however, indicate not less than ten species. The ameba is found not only in the discharges, but also in the pus from the secondary liver-abscesses. Flexner¹ affirms that bacterial association probably has much influence on the pathogenic powers of the amebæ. Hehir has found the *bacillus dysenteriae* associated with the *amœba* and considers it to be pathogenic. The principal causative rôle in the production of this form of dysentery has been ascribed to the pyogenic cocci by Tancarol, Ascher, and others.

The disease is much more prevalent in adult males.

The mode of transference of the ameba is not definitely known, though the principal source of the dysenteric germs is most probably the drinking-water. The disease is feebly communicable by contact.

¹ *Jour. Amer. Med. Assoc.*, Jan. 5, 1901.

Pathology.—The lesions are almost always situated in the large intestine, although rarely the ileum is also invaded. The first visible change is a hyperemia of the mucosa, most marked in the descending colon and rectum; but the changes which produce the characteristic dysenteric ulcer begin with infiltration and swelling of the submucosa, followed by necrosis, which involves the overlying mucosa with its epithelium (Kruse and Pasquale). How the amebæ reach the submucosa has not yet been observed. The infiltrated circumscribed areas are oval or hemispheric in shape, and project above the level of the surrounding mucosa. The submucosa presents a grayish-yellow appearance, and is soon thrown off in the form of a slough.

The ulcers take various shapes—chiefly irregular, and less frequently round or oval. Their edges are ragged and undermined, and the floor, which is more or less covered with pultaceous material, is rough or crater-like, and formed by the musculature or the outer serous coat of the intestine. From the manner in which the ulcers are formed it is obvious that cellular infiltration (followed by necrosis) may occupy the submucosa for a greater or less distance beyond the borders of the ulcers. In this way fistulous channels may be produced beneath the mucosa and connect two or more ulcers. Usually this ulcerative process affects only certain portions of the large gut, especially the flexures—hepatic and sigmoid—and the rectum; but it may be general, and I have seen an instance of this kind. Cases are not uncommon in which the ulcers are so numerous as to include almost the entire mucosa of the colon.

Healing is attended with the development of fibrous tissue along the edges and in the base of the ulcer, and secondary contraction of this new connective tissue is often productive of colonic stricture, which is usually either partial or irregular. The cases that come to autopsy often show diphtheritic inflammation as a secondary or terminal condition.

The *microscope* reveals proliferation of the fixed connective-tissue cells, and the presence of amebæ in the walls and the base of the ulcers, in the lymph-spaces, and rarely in the blood-vessels. Pus can only occasionally be detected.

The *liver* may be the seat of prominent lesions. These are (a) *abscesses*, which may be single or multiple. The single or large solitary abscess is usually situated near either the upper convex or the lower concave surface, while the abscess-cavity is formed in a manner similar to the intestinal ulcers. The area affected is at first infiltrated; it then becomes necrotic, and finally more or less liquefied. Upon the full development of the first stage the part invaded is a grayish-yellow pultaceous mass, but in the second or necrotic stage the abscess contains a yellowish or greenish-yellow, spongy material with beginning liquefaction. The contents of the mature abscess consist of a greenish- or reddish-yellow purulent material and of remnants of liver-tissue. The walls of the recent abscess are irregular and ragged, those of an old abscess being dense and fibrous, and a section of the abscess-wall shows an inner necrotic zone, a middle zone (in which there is great proliferation of the connective-tissue cells, compression and atrophy of the liver-cells), and an outer zone of intense hyperemia (Osler). The contents of the abscess show either few or many amebæ, and only rarely pus. When pus is present it is due to a secondary infection by the

pyogenic germs. The amebæ probably gain access to the liver by metastasis from the intestinal foci. Cultures are generally sterile.

(b) The parenchyma of the liver may be the seat of circumscribed necrotic spots, due to the action of the toxins formed by the amebæ.

The lungs sometimes show changes similar to those in the liver; they are the result of direct extension of the hepatic abscess through the diaphragm into the lower lobe of the right lung. The kidneys often present the lesions of acute parenchymatous nephritis (Craig).

Clinical History.—The mode of onset is *gradual* except in a small proportion of the cases, in which it is sudden with well-marked symptoms. When, as generally happens, it is insidious, the initial symptom is often a trivial diarrhea. The affection is then characterized principally by *intermissions* and an exacerbating *diarrhea*, the liquid stools containing necrotic tissue of a grayish-brown and sometimes yellowish-gray color. The latter are often bloody and mucoid, particularly at the outset, and in fully developed cases are fluid. The *number* of discharges per day is exceedingly variable, although in most instances they range from six to eight or ten daily.

Microscopic examination of the feces during the exacerbations discloses amebæ that are almost invariably endowed with motion, though usually not when the stools have become formed. Tenesmus is not a prominent feature in most cases, and may be entirely absent. Colicky abdominal pains, nausea, and vomiting are rare.

General Symptoms.—Fever is usually present, but it is slight and exhibits marked variations. In certain instances, however, the temperature is below the normal. From the time of onset there is gradual, progressive loss of flesh and strength, and anemia usually becomes well marked.

Complications.—The most common is *hepatic abscess*, and as the result of perforation of the diaphragm may arise secondary abscess of the right lung. Authors are not agreed as to the frequency of occurrence of liver-abscess (see p. 918) in amebic dysentery, but it is certainly comparatively rare in this country, not exceeding, perhaps, 3 per cent. of the cases. In the tropics it occurs in 20–25 per cent. of the cases. *Peritonitis* may result from perforation of a dysenteric ulcer, causing death. The point of perforation may, however, be in the rectum, when *periproctitis* is the result; or it may be in the cecum, when *perityphlitis* is the sequel. In tropical or subtropical countries the disease is often complicated with malaria. The presence of an intermittent fever is not, however, sufficient to warrant the assumption that malaria complicates dysentery; we must be able to demonstrate the presence in the blood of the *plasmodium malarie*. In pyemia and in suppurative processes generally—conditions sometimes met with in dysentery—the temperature-curve is often distinctly intermittent. *Typhoid fever* is a rare complication. The *typhoid state* is met with, and pyemia and septicopyemia may appear late. Pylephlebitis, pericarditis, endocarditis, pleuritis, nephritis (common), and rheumatoid pains in the joints are observed.

Diagnosis.—The slow course, marked by intermissions and exacerbations of the bloody, fluid stools, the mild general symptoms, apart from emaciation and debility, are salient features, but an assured recognition of the affection demands a microscopic examination of the stools.

Cases have been recorded by Councilman and Laffleur in which the diagnosis rested upon amebæ being found in the sputa; this was explained by the existence of an hepato-pulmonary abscess, which had discharged through a bronchus; the intestinal symptoms were negative. Similar cases have been reported by L. Napoleon Boston¹ and others.

Prognosis.—The mortality-rate in certain epidemics has been frightful, particularly among soldiers in the field (amounting to 70 or even 80 per cent.). In sporadic cases the danger to life is less, the mortality-rate in temperate climates being not over 5 or 6 per cent. The complications which render the prognosis unfavorable are various (peritonitis, hepatic and pulmonary abscess, pyemia, broncho-pneumonia, malaria); death may be due to hemorrhage or peritonitis, but in a preponderating proportion of the cases to asthenia. A dangerous degree of debility is indicated by great nervous depression; a cool, clammy skin; a sunken, pinched facies; a dry tongue; a feeble, rapid pulse; and by restlessness, alternating with low muttering delirium.

Course and Duration.—The average duration ranges from eight to ten weeks in uncomplicated cases; the disease can, however, be cut short by appropriate treatment. It manifests an innate tendency to pursue a chronic course, interrupted by frequent exacerbations or true relapses, and convalescence occupies a long period of time in consequence of the profound anemia and debility that supervene.

Treatment.—The diet should consist of easily digestible and nutritious solids, as raw oysters, eggs, well-boiled rice, fowl, fish, and the like, in small quantities. Milk should also be freely allowed. It may be necessary to restrict the diet to fluids if diarrhea be well marked. During convalescence a return to a mixed dietary is to be adopted in a gradual manner.

A judicious hygienic regimen calculated to maintain assimilation is especially valuable. Rest in bed, combined with gentle, systematic massage, may be necessary in severe cases; in other and lighter cases graduated exercise in the open air and rest are serviceable. The medical treatment is by ipecacuanha, in the form of salol-coated pills. Not less than 30 grains at a single dose are to be given on the first day. "Subsequently the amount is to be diminished by five grains *per diem*, so that by the sixth day only five grains of the drug are administered. During the next week or ten days a nightly dose of five grains must be allowed."² Colonic injections of warm solutions of quinin (strength 1 : 1000 to 1 : 5000) have proved effective in the hands of most clinicians. Leroy, of Memphis, has used formalin similarly (1 : 1000), with almost specific effects. A small class of cases do not yield to either the ipecacuanha treatment or rectal lavage; they demand "appendicostomy and systematic, thorough irrigations through the appendix."³ Recurrences will yield to the same means, and they can sometimes be prevented by promoting the repair of the blood and tissues during the intervals.

FLAGELLATA.

MASTIGOPHORA.

During the motile period of their existence these organisms possess one or more flagella attached to either or both ends in the various forms, and some of them also possess an undulating membrane, the trypanosomes being the best exemplars of this latter group. The body of these parasites is very small, many with rounded anterior portion, pointed posteriorly; others, spindle-shaped. They are nucleated, often have vacuoles, and some contain chlorophyll.

Trichomonas vaginalis lives in an acid medium. It is not found in normal vaginal secretion, but in vaginal catarrh with acid secretion; it may occur at any age from childhood to advanced life. It is a specific parasite of the female generative tract, though, rarely, it has been found in the urine of men, probably introduced through coitus. It is not known how they gain entrance to a woman. Alkaline solutions destroy them, as does cold.

Trichomonas intestinalis and *pulmonalis* are met with in stools, urine, sputum, secretions from mouth; but these forms are not pathogenic.

Lambia (*Cercomonas*) *intestinalis*—a monad commonly met with in intestinal discharges; not believed to be pathogenic. Cercomonads have been found (*C. hominis*) in discharges of cholera patients and (*Bodo urinarius*) in urine.

Balantidium coli (*Paramœcium coli*) is found in discharges from obstinate cases of colitis; also in mucosa, and even submucosa, of rectum and colon. Stokvis has found it in the sputum of a case of pulmonary abscess. The pig is believed to be the source from which man is infected.

TRYPANOSOMIASIS.

SLEEPING SICKNESS.

The trypanosoma is a flagellated hematozoön common to the lower animals, and has been found in man. *Trypanosoma hominis* is a minute, colorless, translucent, active protozoön, tapering toward its extremities, the anterior of which displays a long flagellum. The body of the organism is finely granular. It is found free in the plasma. Trypanosomes have been known for over sixty years, but their pathologic import was first pointed out by Evans in surra, a disease of horses and cattle in India, *trypanosoma Evansii*. In May, 1901, Forde found the organism in the blood of an Englishman suffering from an irregular chronic fever, at first thought to be malaria. Six months later Dutton found and recognized the nature of the organism in the blood of this same patient, though about ten years before, Nepven, a French observer, had seen the same or a similar parasite in man, this being the first time that man was found to be subject to infection from trypanosomes. Dutton suggested the name *trypanosoma gambiense* for the parasite, and trypanosomiasis for the disease. Trypanosomiasis is engrossing a large proportion of the professional attention at the present day of Europe, Asia, Africa, Australia, and even America. Castellani¹ found the trypanosoma in

¹ *Lancet*, June 20, 1903.

the spinal fluid, obtained by lumbar puncture, in 20 out of 34 cases of sleeping sickness, but Bruce first showed the pathologic relationship between sleeping sickness and trypanosoma, and that the agent of transmission is the tsetse fly of the genus *Glossina palpalis*. This fly is not found in America.

Trypanosomes have been found associated with many diseases of man and animals, and Manson believes that three of these—*i. e.*, the *trypanosoma Brucei*, a tsetse-fly disease, causing nagana in horses and cattle; *trypanosoma Evansii*, and the trypanosome of mal de caderas—are closely allied species, if not identical. Recently Broeden discovered in the Congo country a trypanosome which is pathogenic for cattle, rats, guinea-pigs, and monkeys, and the infection is essentially like that produced by other trypanosomes.

Symptoms and Diagnosis.—Early the *skin* may appear nearly normal, but Ford and Manson have described blotches of erythema, isolated areas of edema, especially of the eyelids, and, later, general edema and cachexia. The *tongue* is red and raw. There are wasting, general malaise, and decided weakness of the lower limbs. The *pulse* may reach 120 beats per minute. Tachycardia and muscular weakness are the rule. Fever may develop at intervals or may occur daily for an indefinite time, ranging from 100° to 104° F. (37.7°–40° C.). Lethargy is the dominating feature of these cases. In addition to the cutaneous symptoms, which may resemble leprosy, there are restlessness, difficulty in speech, delirium, Cheyne-Stokes respiration, and coma. *Splenic enlargement* and tenderness were present in Ford's case. The lymphatic glands are enlarged and contain trypanosomes. An irregular remitting fever is a leading symptom of the first stage. There is general *anemia* of the simple chlorotic type. Ophthalmoscopic examination may show mottling of the fundus. The Liverpool School of Tropical Medicine maintains that gland palpation is the most efficient means of diagnosis of human trypanosomiasis, other causes for the glandular enlargement being absent.¹ The parasites (*trypanosoma hominis*) are numerous in the blood during the febrile periods. (For technique necessary for its recognition and staining, see Malaria.) *Sleeping sickness*, which is due to a lymphatic infiltration of the brain with small mononuclear cells, probably constitutes the second or final stage of human trypanosomiasis. There is a marked rise of temperature in the evenings. There are mental dulness, headache, general weakness, and somnolence, merging into coma later.

Treatment.—Koch advises the sacrifice of every animal whose blood is found to contain the parasite. He has found arsenic to be a specific in the treatment. The methods adopted by Great Britain and Germany to prevent trypanosomiasis are: segregation, notification, and measures for dealing with animals serving as carriers. Dr. Daniels informs me that atoxyl in ascending doses has been found effective. Commencing with gr. j, every second day, the dose is increased to gr. iiss at the end of one week, to gr. ij at the end of another week, then gr. iiss to gr. iiij every second day for a year or more after all trypanosomes have disappeared. This treatment may be followed by a course of mercury. Excellent reports from the use of Ehrlich's remedy (arseno-phenyl-glycin) have been received, but is still on trial.

¹ J. L. Todd, *The Journal of Tropical Medicine and Hygiene*, October 15, 1908.

FEBRILE TROPICAL SPLENOMEGALY.

(Dumdum Fever, Kala-azar, Piroplasmosis.)

Definition.—It is a chronic disease, characterized by anemia, irregular fever, emaciation, pigmentation of the skin, enlarged spleen, and by a protozoön organism, which is found in the spleen, liver, bone-marrow, lymph-glands, adrenals, testicles, intestinal and cutaneous ulcers, and inflammatory exudates, and only very rarely in the blood.

Tropical splenomegaly, known also by its native Indian name, kala-azar (black fever), from the pigmentation of the skin, has also been termed Dumdum fever in Indian medical circles, after Dumdum, a military station near Calcutta. The disease is met with in India, Assam, China, Egypt, and Africa. Epidemics move forward very slowly—about 14 miles a year—the disease clinging to a place for almost five years and then disappearing.

Etiology.—In 1885 Cunningham, and in 1901, Firth, called attention to certain minute bodies to be found in the protoplasm of the cell exudate of the base of the Oriental sore or Delhi boil. In November, 1900, Leishman found these bodies in smears from the spleen of a case of Dumdum fever in a soldier invalided home from India. In the winter of 1902–3 Major Leishman noted these same organisms in smears of blood and internal organs from a trypanosome-infected rat. In May, 1903, he published these observations, and suggested that the organisms were trypanosomes. Soon after Donovan found them in fluid obtained by splenic puncture from an Indian, hence the name, Leishman-Donovan body. Low, Manson, Rogers, Bentley, and others have since found them. They are minute, oat-shaped, oval, or round bodies, with faintly staining protoplasm, but deeply staining chromatin masses, usually placed at opposite poles of the cell. Rogers succeeded in cultivating these bodies in citrate of soda solution, typical flagellated organisms resulting—the proof of their nature. Unlike the usual type of trypanosomes, the flagellum is attached to the end of the body at which the micronucleus is situated, and it does not possess an undulating membrane. It probably escapes from the body of the infected individual in the discharges from cutaneous or intestinal ulceration, and in all likelihood the intermediate host is some biting insect.

Predisposing Causes.—One-third of the cases occur under twenty years of age, and the Hindus were more frequently affected by the disease than the Mohammedans, the proportion being about 4 to 1 (Brahmachari).

The Oriental sore—Delhi or Bagdad boil, a local infection, without constitutional symptoms—is apparently due to the same trypanosome as tropical splenomegaly, but it is not fatal, and one attack, as a rule, gives immunity. Manson says it has been noted that Oriental sore is peculiar to camel-using countries, and if this really be due to the same Leishman-Donovan body as kala-azar, that a reduction in virulence of the organism has been attained by passage through the camel, as is the case with small-pox in its passage through the cow. The inference is, therefore, that the virus of Oriental sore should be employed in an attempt to protect against kala-azar. The disease prevails at all ages, in both sexes, and shows a predilection for the natives and old residents.

Symptoms.—There is fever, irregular in type, generally remittent, often comparatively long intermittent periods, the whole extending over some months. The fever may occur in ague-like attacks. A dirty, sallow, anemic appearance of the cutaneous surface is noted, and occasionally areas of pigmentation. Enlargement of the spleen and liver,

occur early, the former being an invariable accompaniment, while the latter is less constant. Dyspnea, emaciation, progressive and, finally, extreme weakness, and more or less edema are present. Leucopenia, in which the proportion of white or red corpuscles may be less than one to one thousand with relative low polymorphonuclear counts, is almost diagnostic of the disease. Cutaneous and intestinal ulceration develop various hemorrhages or purpura, and these, in an extremely emaciated individual with a large protuberant belly, make a picture fairly characteristic. Death often results from some intercurrent affection. Among the commoner complications are pneumonia, pulmonary tuberculosis, abscesses, and splenalgia due to infarcts in the spleen.

Prognosis.—Manson regards the disease as absolutely hopeless; he has never seen a case recover. Rogers places the mortality at 96 per cent. Donovan gives an equally gloomy prognosis.

Treatment.—Tonic and hygienic. Quinin is of no special value, but may be employed with iron and arsenic. When possible, segregate infected cases, since no other known method of prevention exists, and, as we have seen, once developed, it proceeds to a fatal issue.

PSOROSPERMIASIS.

Psorosperms belong to the lowest form of protozoa. They are also known as *sporozoa*, and, because of their parasitic relation to cells, as *cytozoa*. A common form occurs in the muscles of the pig (*sarcocystis Miescheri*). The *ameba coli* of amebic dysentery belongs to the protozoa. Various coccidia may occur in man (e. g., *sarcocystis hominis*) to produce the disease indicated by this heading.

(a) *Internal Psorospermiasis.*—In man, hepatic disease similar to that found in the rabbit is produced by the *coccidium oviforme*. The tumors formed by the coccidia may be palpable, and the liver may be quite tender. Some chilliness and fever, malaise, and stupor passing into coma have been observed. Death was caused on the fourteenth day in a case admitted to St. Thomas's Hospital (Osler). The necropsy showed whitish neoplasms in the peritoneum, omentum, kidneys, pericardium, liver, and spleen.

In the intestinal variety of *internal psorospermiasis* nausea and vomiting, diarrhea, and the typhoid state may be manifested. Involvement of the kidneys has caused hematuria and frequency of urination.

(b) *External Psorospermiasis.*—*Cutaneous psorospermiasis*, one form of which was formerly called *keratosis follicularis*, is characterized by lesions at first of a hard, crusty, papular type, later becoming confluent, and situated on the face, lumbo-abdominal, and inguinal regions. These papillomatous growths contain either parasitic sporozoa, or, as suggested by Montgomery and others, parasites that belong to the blastomyces.

In carcinoma, epithelioma, and Paget's disease of the nipple coccidia are readily found in and between the pathologic epithelial cells, but whether they have an etiologic bearing upon these malignant affections is still a matter of uncertainty.

Prophylaxis consists in cleanliness and care in preparing such food vegetables as spinach, lettuce, cabbage, and other greens that may possibly be contaminated by the excreta of the lower animals liable to psoroform-infection. The **treatment** of psorospermiasis is symptomatic, though rectal injections of a solution of quinin (1:5000 to 1:1000) may be tried.

DESCRIPTION OF PLATES III. AND IV.¹

The drawings were made with the assistance of the camera lucida from specimens of fresh blood. A Winckel microscope, objective $\frac{1}{4}$ (oil immersion), ocular 4, was used. Figures 4, 13, 23, 24, and 42 of Plate III. were drawn from fresh blood, without the camera lucida.

PLATE III.

THE PARASITE OF TERTIAN FEVER.

- 1.—Normal red corpuscle.
- 2, 3, 4.—Young hyaline forms. In 4, a corpuscle contains three distinct parasites.
- 5, 21.—Beginning of pigmentation. The parasite was observed to form a true ring by the confluence of two pseudopodia. During observation the body burst from the corpuscle, which became decolorized and disappeared from view. The parasite became, almost immediately, deformed and motionless, as shown in Fig. 21.
- 6, 7, 8.—Partly developed pigmented forms.
- 9.—Full-grown body.
- 10-14.—Segmenting bodies.
- 15.—Form simulating a segmenting body. The significance of these forms, several of which have been observed, was not clear to Drs. Thayer and Hewetson, who had never met with similar bodies in stained specimens so as to be able to study the structure of the individual segments.
- 16, 17.—Precocious segmentation.
- 18, 19, 20.—Large swollen and fragmenting extracellular bodies.
- 22.—Flagellate body.
- 23, 24.—Vacuolization.

THE PARASITE OF QUARTAN FEVER.

- 25.—Normal red corpuscle.
- 26.—Young hyaline form.
- 27-34.—Gradual development of the intracorpuseular bodies.
- 35.—Full-grown body. The substance of the red corpuscle is no more visible in the fresh specimen.
- 36-39.—Segmenting bodies.
- 40.—Large swollen extracellular form.
- 41.—Flagellate body.
- 42.—Vacuolization.

PLATE IV.

THE PARASITE OF ÆSTIVO-AUTUMNAL FEVER.

- 1, 2.—Small refractive ring-like bodies.
- 3-6.—Larger disk-like and ameboid forms.
- 7.—Ring-like body with a few pigment-granules in a brassy, shrunken corpuscle.
- 8, 9, 10, 12.—Similar pigmented bodies.
- 11.—Ameboid body with pigment.
- 13.—Body with a central clump of pigment in a corpuscle, showing a retraction of the hemoglobin-containing substance about the parasite.
- 14-20.—Larger bodies with central pigment clumps or blocks.
- 21-24.—Segmenting bodies from the spleen. Figs. 21-23 represent one body where the entire process of segmentation was observed. The segments, eighteen in number, were accurately counted before separation, as in Fig. 23. The sudden separation of the segments, occurring as though some retaining membrane were ruptured, was observed.
- 25-33.—Crescents and ovoid bodies. Figs. 30 and 31 represent one body, which was seen to extrude slowly, and later to withdraw, two rounded protrusions.
- 34, 35.—Round bodies.
- 36.—"Gemmation," fragmentation.
- 37.—Vacuolization of a crescent.
- 38-40.—Flagellation. The figures represent one organism. The blood was taken from the ear at 4.15 p. m.; at 4.17 the body was as represented in Fig. 38. At 4.27 the flagella appeared; at 4.33 two of the flagella had already broken away from the mother body.
- 41-45.—Phagocytosis. Traced with the camera lucida.

The Parasite of Tertian Fever.

The Parasite of Quartan Fever.

The Parasite of Aestivo Autumnal Fever.

is the fact mentioned in the description of the amebæ (*infra*) that the hemoglobin of the blood is converted into melanin (pigment) by the organisms. The malarial parasite also engenders a *toxin* which may be in part responsible for the morbid lesions of the disease.

The spleen is engorged with blood, and at first is swollen (chiefly during the febrile paroxysm), but it soon becomes permanently enlarged ("ague-cake"). A rare accident in intermittent fever is rupture of the spleen. Hemorrhagic infarcts are occasionally presented by this organ.

The liver is also engorged, but not to the same extent as the spleen.

The heart-chambers may be found to be acutely dilated. Neuritis has been observed by Gowers, Bamstark, Ewald, and V. P. Gibney. W. G. Spiller¹ reported a case that showed partial sclerosis of the motor tracts, and recent hemorrhages within the left internal capsule (*vide* Pernicious Malarial Intermittent, also Remittent Malarial Fever, *infra*).

Etiology.—Parasitology.—Our knowledge of the malarial parasite may be discussed under five heads: (1) Discovery of the *Plasmodium malarie* in the blood of persons suffering from the disease. (2) Its developmental cycle in man (sporulation), as shown by Golgi, in 1885. (3) The discovery, by MacCallum, of its method of sexual fertilization. (4) Its fertilization and development in an intermediate host (the mosquito), as first pointed out by Surgeon-Major Ross. (5) The observations of the Italian school, showing its method of re-entering the tissues of man.

(1) In 1880 Laveran discovered the malarial parasite, but it was not until 1883, when Marchiafava, Celli, and Golgi published their confirmatory investigations, that the profession accepted the parasitic origin of the disease.

(2) Laveran and Golgi observed that certain parasites, especially those found in estivo-autumnal fever, developed into peculiar crescentic bodies (gametocytes). Other more rounded, ring-like bodies were seen to display abnormal agitation in from ten to fifteen minutes after being withdrawn from the body, followed by the discharge from the protoplasm of several filamentous bodies or flagella (microgametocytes). The latter were seen to separate from the parent-cell, after which they were observed swimming independently in the blood.

(3) The significance of both the crescentic and flagellated bodies was first described by W. G. MacCallum, of the United States, in 1897. While studying the life-history of the "halteridium," it was noted that a limited number of ellipsoid bodies were produced, corresponding to the crescentic bodies seen in human malaria. Certain of these bodies were hyaline, others granular, and it was the former variety only that developed flagella. A flagellum, on swimming away from the mother-cell, was seen to display peculiar agitation on approaching one of the granular bodies (crescentic). One of the flagella was seen to enter the granular body and effect a symbiosis with it (*sexual fertilization*). Fertilization was followed by a short rest, after which the granular body assumed a worm-like form, and then swam slowly away, its pointed end directed foremost and trailing behind it pigment particles, which had been situ-

¹ *Amer. Jour. Med. Sci.*, Dec., 1900.

ated within its protoplasm. Later MacCallum was able to confirm these investigations by a microscopic study of the blood from a case of malaria (estivo-autumnal) in man, the flagella being formed after exposure to the air. In human malaria sexual fertilization takes place in the mosquito's stomach or middle intestine within the first twelve hours.

(4) Manson correctly supposed that the mosquito sucked blood from malarial subjects. Surgeon-Major Ross,¹ of Liverpool, began his investigations in India, in 1895, by endeavoring to determine what became of the parasite after fertilization in the mosquito's stomach. During August and September, 1897, two members of the species *Anopheles maculipennis*, bred from the larvæ, were fed on the blood of patients containing crescents, and he found that peculiar spheroidal cells developed on the walls of their stomachs, which convinced him that "these cells constituted the long-sought mosquito stage of the parasite" (*zygote*).

In 1898 Ross studied the "zygotes of protozoma" of birds. He found that they attached themselves to the outer coats of the mosquito's stomach. The zygote grows rapidly, without movement or change in form, protruding into the insect's body-cavity. Later its capsule becomes easily perceptible and the cell-substance is seen to divide into from ten to twelve "meres." In from one to three weeks, depending on the external temperature, the zygote matures, when each mere contains a number of delicate, "thread-like" blasts.

The next step in the development of the parasite is the rupture of its capsule, setting free these "thread-like" blasts within the insect's body; they are then carried by the blood's currents to all its tissues, more particularly into the insect's salivary gland. The common duct of the salivary gland of the mosquito (genus *Anopheles*) passes along the middle stylet of the proboscis, opening at its extremity, and a portion of the secretion of this gland is poured into the wound caused by the insect's bite. In the human body the blasts return to the amebulæ, with which the life-history of this parasite began.

(5) In 1898 Grassi found three chief species of the mosquito in malarious localities, the *Anopheles claviger* being constantly present. Manson gives 32 members of the family Anophelinae, which have been shown, with more or less precision, to be hosts of the malarial parasites. Banks has shown conclusively that *Myzomyia ludlowi* should be added to the list.

In Nov., 1898, Bastianelli, Bignami,² and Grassi conducted a series of experiments, by feeding mosquitoes the blood from persons suffering from estivo-autumnal fever, confirming the findings described by Ross, in Aug., 1897. These investigations showed the *mode of infection*; that healthy mosquitoes become infected by sucking blood from malarial patients, and that in from eight to twenty-one days such insects may infect healthy men by their bites. One mosquito may infect many persons, and may possess this power for an indefinite period, "since not all of the germinal threads escape from the venomosalivary gland."³ Neither the common house mosquito (genus *Culex*) nor the *Anopheles nigripines* takes part as an intermediary host for this parasite. The fact that mos-

² "Malaria and Mosquitoes," *Lancet*, Jan. 13, 1900.

³ *Jour. Amer. Med. Assoc.*, Feb. 3, 1900, A. Woldert.

quitoes (*Anopheles claviger*) are known to occupy non-malarious districts proves the innocence of the uninfected insects. A single case of malaria transported to such territory often results in an epidemic.

The malarial parasite of Laveran belongs to a subclass of the protozoa known as hematozoa (*hæmameba*). Of the latter, three varieties, corresponding with the three leading clinical forms of the affection, have been distinguished in man, and the evolution of two of these parasites at least takes place within the red blood-corpuscles. Manson describes five species which he classifies as follows:

| | | |
|-----------|------------------------|------------------------|
| Benign | { Tertian Quartan } | do not form crescents. |
| | | |
| Malignant | Quotidian—pigmented | { form crescents. |
| | Quotidian—unpigmented | |
| | Tertian | |

They enter the red cells in the form of small, non-pigmented plasmodia, exhibiting ameboid motion, and then feed upon their host, transforming, at the same time, the hemoglobin of the latter into dark pigment-granules as they develop. The special varieties of the malarial parasite as observed in microscopic studies of the blood of human beings will be described separately.

(1) *The Hæmameba Causing Tertian Intermittent Fever.*—This begins its asexual cycle of evolution in the red blood-corpuscles as a small hyaline ameba. Its development is attended with the appearance in its interior of fine, brown, motile granules in the form of pigment, and when matured it about equals the size of a normal red corpuscle. It now assumes a spheric form, the pigment collecting centrally, and sporulation into fifteen to twenty or more segments follows. The tertian parasites are exceedingly numerous in the blood, and pass through the various stages of their life-cycle almost simultaneously, the sporulation of an entire generation occurring within the space of a few hours (Golgi). The occurrence of the malarial paroxysm follows the process of sporulation, which is attended, most probably, with the development of a toxin, and the symptoms of the disease may be attributable chiefly to the effects of the latter. The red corpuscle that includes the parasite becomes enlarged and decolorized as the latter develops. The parasite of tertian intermittent runs its cycle in about forty-eight hours. Hence infection by a single generation would result in sporulation every second day, followed by the malarial paroxysm. Quite commonly, infection by two groups of parasites occurs on successive days, and, since each has a definite period of evolution, a daily malarial paroxysm is the result (quotidian intermittent). Multiple infection with this parasite may occur, but with great rarity.

(2) *The Hæmameba Causing Quartan Fever.*—This cannot be distinguished from the tertian parasite at the beginning of its asexual career, but later differences are clearly perceptible. Its ameboid movements are more deliberate, and its pigment-granules are coarser, darker, and also less motile than those of the tertian organisms. Unlike the latter, it does not attain the size of the red corpuscles, and during sporulation the segments (five to ten in number) encircle in an orderly way the central pigment-mass or clump, "rosettes" of great beauty thus being formed.

The red blood-corpuscle that harbors the quartan parasite contracts upon its destroyer, appears shrivelled, and its color changes at the same time from the normal to a deep greenish or bronzed tint. It sporulates about seventy-two hours after it enters the red corpuscle; hence, if only one group of parasites be present, febrile attacks occur every fourth day—quartan intermittent. On the other hand, double quartan infection results in paroxysms on two successive days, followed by an intermission lasting one day, while triple infection, or the presence of three groups, causes daily paroxysms—the quotidian intermittent. Infection by more than three groups of the quartan parasite may occur, but is very rare.

(3) *The Hæmameba Causing Estivo-autumnal Fevers*.—The endogenous cycle of this variety is evolved, chiefly, in certain of the internal viscera, and the microscopic examination of the blood in the various stages of the disease does not always give a positive result, as in benign tertian and quartan. The organism invades the red blood-corpuscle, but to what extent is questionable. It is a quite small hyaline body, its size at maturity scarcely equalling one-half the dimensions of the red corpuscle, and it accumulates very few fine pigment-granules. The parasite may be found in the later stages in the blood from certain internal viscera, as the spleen. After the condition has lasted a time characteristic oval and crescentic bodies, which are more or less refractive, may be observed in the fresh blood. These so-called “sickle-form bodies” show central rods and clumps of coarse pigment, and are especially connected with the malignant type of malarial fevers. Ring-form bodies, and, at times, the signet-ring forms, are observed. The red corpuscle, at whose expense the parasite develops, assumes a brassy-green hue, becoming shrivelled and often crenated.

It would appear from the studies of Manson, Marchiafava, Big-nami, and Surgeon Craig¹ that two varieties of parasite are concerned—quotidian and tertian forms of autumnal fevers (*vide* table, p. 345).

The parasites of tertian estivo-autumnal fever are larger than the quotidian parasite, and during the hyaline stage the signet-ring form, sluggish ameboid movement, clear-cut refractive outline, and the occurrence of one organism in a blood-cell which is not wrinkled are observed; during the pigmented stage, the ameboid movement and fine granular motile pigment. Segmentation takes place outside the corpuscle. Crescents are large, slender, and deeply pigmented (see Plate IV., p. 346).

The quotidian parasite is smaller, at times actively ameboid, and more than one parasite may occupy a single red cell, which is usually wrinkled. Their pigment is motionless, and usually in the form of short rods. Unpigmented parasites also occur (Manson). Crescents are small, plump, and often present a double outline. Segmentation occurs within the red corpuscle.

Development of Flagella.—Some of the crescents become ovoid with scattered pigment; this in turn becomes more or less spherical, the pigment forming a central ring; “this finally approaches the periphery, the whole parasite becomes violently agitated, throwing out flagella, which have a wave-like motion, many of which break away” (Wright).

Predisposing Causes.—(1) *Soil*.—Fresh-water marshes favor the development of malaria, and are most fruitful in influencing its growth

¹ *New York Med. Jour.*, Dec. 23, 1899.

when located near the coast and tainted with salt water. Again, marshy districts affording luxuriant vegetation are notorious as malarial foci. Keeping in remembrance the foregoing facts, we can readily see why malaria is unusually prevalent in certain countries (chiefly tropical), and why it is chiefly confined to the low-lying estuaries and the deltas of rivers. The same facts explain satisfactorily why certain districts which were very liable to the affection should have become, as the result of denudation of the virgin soil and its subsequent drainage and cultivation, entirely free from the complaint. Epidemics following the upturning or the removal of the surface of the virgin soil are probably due to importation of the disease (or infected mosquitoes), and are common on the frontier of the South and West.

(2) **Climate.**—Malaria is more prevalent in tropical and subtropical than in temperate climates, and more common in the latter than in the polar zones. Hence it occurs more frequently in the southern than in the northern States of our own country.

(3) **Rapidly growing trees** dry the soil by absorbing enormous quantities of water. In the Roman Campagna extensive experiments have been made with the eucalyptus tree, and districts protected in this manner becoming almost entirely free from malaria in a few years, the environment being unsuited to the mosquito.

(4) **Seasons.**—In temperate latitudes most cases are developed in the autumn, the maximal period corresponding with the month of September. This dictum is based upon 4841 cases of malaria gathered by the author from the records of the leading Philadelphia hospitals.¹ Cases that develop before the "*Anopheles claviger*" makes its appearance (in June) are possibly relapses. In the tropics the case seems to be different, and two maximum periods—spring and autumn—obtain. Statistics from the hospitals of Rome, collected from 1864 to 1898, show the maximum number of cases to occur in August, September, October, November, and July, respectively, and in June the minimum number.

(5) Persons occupying the upper stories of a house or living on slight elevations are affected with relative infrequency, for the reason that mosquitoes are always found near the earth's surface, where the air-currents are feeble. This fact also explains the nocturnal infection.

(6) **Race** exerts little influence, but in the United States negroes are slightly less susceptible than are the whites.

(7) **Sex** is without effect when men and women are equally exposed. Cases are, however, vastly more frequent among males because of their increased liability to mosquito bites while following certain occupations (agriculture, marsh-draining). The 5044 cases collected by me gave the numerical proportion of 6 to 1 in favor of males.

(8) **Age.**—Children are more susceptible than adults.

Immunity.—There are individuals immune from malaria and experimental malaria. An individual may present this property after a mild fever has been cured by quinin. Maurel has shown that when living in a malarious district whites may in time show marked immunity. By the use of methylene-blue and euchinin an immunity may be established against the inoculation of from 1 to 2 grams of estivo-autumnal blood.

¹ *Univ. Med. Mag.*, May, 1897.

Incubation.—According to Bignami and Bastianelli, the period of incubation for experimental malaria is: Quartan, 15 days; spring tertian, 12 days; estivo-autumnal tertian, 5 days. The administration of potassium bromid, potassium iodid, arsenic, carbolic acid, antipyrin, and phenocoll may result in a longer period. Angelo Celli has seen spring tertian show incubation of 22, and the estivo-autumnal tertian 17 days.

Epidemiology.—Estivo-autumnal fevers are rare in their recurrence, while mild tertian and quartan prevail with each new spring, and the first cases of tertian are noted to occur in the same houses in which the last recurrences of these fevers appeared. After the first cases there is a lapse of from seventeen to eighteen days, after which the epidemic spreads. The life and habits of the *Anopheles* have a direct bearing upon epidemics—"either the first cases of these fevers in July are recurrences of a previous infection, or the very first cases of these fevers in July are primary" (Celli). "Both hypotheses are possible. In both we have to deal with a contagion circulating, so to speak, between the temporary host (man) and the definitive host (mosquito), a contagion which, by means of the blood of the relapsing cases of the preceding year, is transmitted by the agency of mosquitoes, and starts the epidemic of the following year." There are many interesting questions not yet explained.

(I.) **Intermittent Fever.**—**Symptoms.**—The clinical history presents itself under two heads: (a) the paroxysms, and (b) the manner in which the paroxysms recur.

(a) *The Paroxysms.*—There may be premonitions lasting from one to several days, and most significant, yet not distinctive, are headache, pain in the nape of the neck, yawning, a yellowish complexion, and a slight splenic enlargement. In a large proportion of the cases, however, the onset is abrupt. Typical paroxysms present three stages—*chill*, *fever*, and *sweating*. The chill is intense, causing shivering, and often chattering of the teeth. Malaise is marked, the skin is cool and pale, face slightly cyanotic, and limbs painful. This stage usually occurs in the morning hours, but the time of onset is not constant; its duration, also, varies greatly, generally lasting from one to two hours. The internal temperature rises rapidly; the pulse is small, rapid, and of high tension.

The *hot stage* succeeds the chill, and, in striking contrast with the first stage, the face wears a decided flush and the skin is burning hot to the touch. The temperature continues to rise, but not so rapidly as in the first stage. Its maximum level, usually from 104° to 106° F. (40° to 41° C.), is soon reached, and may either be maintained uniformly for several hours, or the curve may show two small summits if the temperature be recorded frequently (Fig. 26). The pulse is full and bounding, except in the rare instances in which acute dilatation of the heart ensues, when it is quite feeble and sometimes irregular. The length of the second stage is from three to six hours. The temperature generally begins to decline before the close of the febrile stage.

When *sweating*, which soon becomes profuse, sets in, the symptoms of the hot stage are promptly relieved. The temperature falls by crisis, touching the normal level in a few hours; the decline, however, is less

rapid than the rise at the beginning of the paroxysm. The fall may be unbroken by any fresh elevations of temperature, though more often the latter occur. Less frequently defervescence occurs by steps, the temperature falling one or more degrees, and remaining at the new level for a short period; then dropping again about an equal distance, and so on until the normal is reached. Usually, following the paroxysm, the temperature becomes subnormal (about 97° F.— 36° C.). The length of the typical malarial paroxysm ranges from eight to twelve hours.

FIG. 26.—Temperature-curve in a case of double tertian fever. C. F. C., aged forty-one years.

(b) *The Manner in which the Paroxysms Recur.*—The special characteristic of this form of intermittent is the regularity with which the paroxysms recur in cases that are not under treatment. The intermission, or time between two successive paroxysms, is most frequently twenty-four hours (quotidian intermittent fever); almost as often it is forty-eight hours (tertian intermittent); and less frequently it is seventy-two hours (quartan intermittent). If there be two paroxysms on

one day—a rare occurrence—the term “double quotidian” is used to designate the case. Of the above types, as stated in the life-history of the parasite, three only—the *quotidian* (malignant), the *tertian*, and the *quartan*—have been clearly distinguished. The quotidian ague (the most frequent clinical variety) is generally due either to double infection by the tertian parasite or the quotidian parasite (single infection), and rarely is it to be attributed to the presence of three groups of the quartan parasite, resulting in daily sporulation. It sometimes happens that the paroxysms recur a couple of hours later each successive day, when it is called a “*retarding*” intermittent fever, or they may recur a little earlier, when the term “*anticipating*” is employed.

Other More or Less Characteristic Symptoms.—Apart from the paroxysms and the regularity with which they recur, *splenic enlargement* is almost always present, and hence is of considerable clinical import. After the first paroxysm or two the swelling is usually marked and demonstrable, especially by palpation. The organ can be shown to increase in size with each succeeding paroxysm. Tenderness is elicited on pressure, and commonly outlasts the course of the affection for a considerable length of time. Moderate enlargement of the liver may be present, but this is not so constant as enlargement of the spleen.

Connected with the *skin* are two symptoms of considerable diagnostic value: (1) a *yellowish-brown discoloration*, the so-called “malarial complexion,” due to the deposition of pigment; and (2) *herpes*. The latter occurs usually on the prolabia or on the nose, though rarely elsewhere. Other skin-eruptions, as urticaria and purpura, have been described by authors, but they have no real clinical worth.

As stated under Pathology, *acute dilatation of the heart* may develop, attended with the usual physical signs of this condition, but it rarely lasts longer than the brief febrile paroxysm. Murmurs of functional origin may also be heard in the heart during the attack, and the *lungs* upon auscultation sometimes present the signs of a dry bronchitis.

The *urine* may contain a small amount of albumin, and rarely there is acute nephritis—a rather common sequel in the negro. There is a temporary increase in the amount of urea eliminated, and this may be observed from two to six or eight hours before the chill, so that an approaching paroxysm can be foretold if a quantitative analysis of the urine be made at the proper time (Jaccoud).

Gastro-intestinal symptoms may be present, as diarrhea which is sometimes considerable, *catarrhal jaundice*, and paroxysmal vomiting, but these are limited to the graver forms of intermittent.

There is a rapid diminution in the number of both red and white corpuscles, proportionate “to the severity and the number of the attacks” (W. W. Johnston). The leukopenia is associated with an increase of large mononuclear leukocytes. The hemoglobin is reduced and granules of pigment are found in the plasma.

Clinical Varieties.—Besides the typical attacks, *mild* or *rudimentary* forms are met with, these either being due to slight infection or appearing as the remnant of cases of usual severity after active treatment. The separate stages of the febrile attacks are not well marked, and one or more may be missing; thus the chill may be absent (dumb ague).

In *children* there is no rigor noticeable. They grow pale, the mucous membranes often being slightly livid during the chill, and the paroxysms

may be initiated by a convulsion or other nervous phenomena. Acute nephritis is a rather frequent sequel in white children.

(II.) **Pernicious Malarial Intermittent.**—This truly serious form occurs chiefly in highly malarial districts, and rarely also in the widespread regions in which the simple variety prevails. In the United States it is encountered most frequently in the Southern and Southwestern States. In this form of malaria the parasites of estivo-autumnal fever are constantly associated. The paroxysms do not recur with strict regularity, and the primary paroxysms are rarely pernicious in character; but second or subsequent attacks may present the gravest phenomena.

Pathology.—This type of malaria may arise (1) as a fresh infection, and (2) as a reinfection.

(1) *Infection.*—The blood is more or less hydremic, and the blood-disks are in all stages of disintegration. The *spleen* is considerably swollen, soft, and its parenchyma is turbid and lake-colored, all its tissue elements being more than naturally pigmented, though this may not be macroscopically appreciable. Upon microscopic examination, however, pigment-granules and red corpuscles containing parasites and phagocytes are observed, particularly in the pulp adjacent to the arterioles. The *liver* is enlarged, soft, and turbid, and pigmentation occurs, but it is also microscopic. In the minute vessels phagocytes and parasites containing pigment are perceptible within the red corpuscles, and numerous small necrotic areas have been observed. The *kidneys* show microscopic pigmentation, most marked in the vicinity of its blood-supply. Minute areas of cell-death are sometimes seen. The *brain* may be abnormally colored, assuming in severe cases a chocolate tint, and in mild types a lighter hue. The brain-tissue is often anemic, and more rarely edematous. Occasionally there is congestion. The capillaries are literally blocked with phagocytes and blood-disks more or less disintegrated (containing parasites), and perivascular infiltration and minute hemorrhages may rarely occur, producing a focal lesion.

(2) *Reinfection.*—The blood is often extremely hydremic. The *spleen* may or may not be much enlarged, and is usually quite firm, with a well-marked pigmentation that is obvious to the naked eye. The *liver* is, as a rule, moderately increased in size, and is somewhat indurated, while macroscopically it is seen to be deeply pigmented. The changes presented by the *kidneys* differ in no essential manner from those of the liver. The microscopic appearances of the liver, spleen, and kidneys, apart from the fact that the amount of pigment present is relatively greater, are entirely analogous to those met with when a fresh infection occurs. Pigmentation of the lung is also common.

Clinical Varieties.—Three varieties merit description:

(a) *Congestive Chills (Algid Form).*—These are accompanied by raging gastro-intestinal symptoms (vomiting, purging, etc.), inducing systemic collapse, which simulates to a nicety the algid stage of cholera. The temperature of the interior of the body is much elevated. True dysenteric symptoms may arise, and sometimes jaundice, followed by grave nervous symptoms, may be a secondary development. The intellect is unclouded, as a rule. This condition is to be discriminated from yellow fever, with which it has frequently been confounded. The parasites in this affection center in a special manner in the gastro-intestinal

mucosa, in the vessels of which they may be seen in unusual numbers, sometimes forming distinct thrombi. In the United States this is the most common among the pernicious forms.

(b) *Hemorrhagic Pernicious Malaria*.—In this form the chill is severe and prolonged, and during the hot stage the urine is bloody and scanty, containing considerable albumin, with bloody, epithelial and granular casts. Hemorrhages from other outlets of the body (mouth, rectum, vagina, nares, stomach) may also occur, together with larger and smaller cutaneous ecchymoses, and the yellowish-brown malarial complexion is intensified. The mind may remain clear throughout, although the patient is restless and anxious. Urinary suppression may ensue, and uremic toxemia be superadded; the greatest dangers being cardiac failure, uremia, and delirium (or coma independently of the latter). Death is rarely the direct consequence of excessive loss of blood.

(c) *Comatose Form*.—The chill may be absent. Grave cerebral symptoms, as acute delirium or sudden coma, seize the patient violently. The hot stage is attended with high fever, and if the patient survives the paroxysm, the violent nervous symptoms either disappear suddenly with the appearance of the sweating stage, or may outlast the latter by several hours. Primary paroxysms rarely prove fatal, but recurrences bring imminent danger. This dangerous variety is due to an inordinate localization of the malarial parasites in the brain, where they form complete thrombi, and induce, as a consequence, pathologic lesions in the adjacent structures.

(III.) **Remittent or Continued Malarial Fevers (Estivo-autumnal Fever)**.—On account of the intensity of the gastro-intestinal symptoms this variety is also termed *bilious remittent fever*. Its severity exceeds that of intermittent malarial fever. It prevails for the great part in warm and truly tropical climates, though it is also seen in its milder forms in temperate climates. The estivo-autumnal parasites previously described are the specific cause of the disease.

Pathology.—Melanosis of the spleen, liver, and brain is generally observed; on the other hand, in rare instances in which the specific parasite had even been demonstrated during life, the internal organs were found to be non-pigmented on autopsy. The degree of the pigmentation depends upon the length of time that the patient has been infected, as well as upon the frequency of reinfection. The *spleen*, if it be a fresh infection, becomes swollen, but is soft; in protracted cases it becomes permanently enlarged and firm. Microscopically the pigment is seen to be most abundant in the splenic pulp and within and around the splenic veins. The *liver* is enlarged in like manner. The pigment that is found in the form of granular masses in all the hepatic tissue-elements (especially Kupffer's cells, vessels, vessel-walls, and perivascular tissue) gives to the organ a bronzed appearance ("bronze liver").

As in pernicious malaria, so in this affection, the *brain*, and particularly the gray matter, is in long-standing cases of a dark brown or almost black color. The *arterioles* are often found stuffed with phagocytes and blood-disks which contain pigmented parasites. Punctate hemorrhages may occur in the brain. The *kidneys* are pigmented and may show "a severe acute degeneration of the cortical tubule cells" (Ewing). Massing of the parasites in the renal capillaries may occur. Other organs and tissues of the body, including the *lymphatic glands and the skin*,

become more or less deeply pigmented. The *blood* shows marked hydre-mia, with partly or wholly degenerated red blood-disks in abundance.

Symptoms.—There may be *prodromal* symptoms, such as headache, anorexia, and epigastric oppression, lasting a day or two, but these signs are variable. There may be daily or bi-daily paroxysms of fever which resemble the ordinary quotidian and tertian intermittent forms, with this difference, however, that the febrile paroxysms are of longer duration (twenty hours or more). Both the rise at the onset and the decline at the end of the paroxysm are more gradual than in true intermittent malarial fever, and the initial chill may even be wholly absent. The febrile attacks are often “anticipating,” so that it may happen that the succeeding paroxysm will begin before the elevated temperature of the preceding touches the normal level, giving rise to a remittent type of fever which often exhibits considerable irregularity. The remissions may become shorter and shorter, producing finally a continued type of curve—*continued malarial fever*.

In *typical cases* of remittent fever a chill generally occurs at the onset, but is less severe than in malarial intermittents. Shortly after the chill the temperature rises rapidly, so that in ten or twelve hours it may reach 104° or 105° F. (40.5° C.). The *pulse* is full and accelerated to 100 or 120, and there is rending headache. Nausea and vomiting are common; oppression in the epigastrium is intense, and there is well-marked tenderness in the latter region. The *spleen* is found to be enlarged on palpation. *Nervous symptoms* (delirium, coma, etc.) may develop speedily, and rarely a mild bronchitis may also arise.

About midnight the *remission* in the temperature and sweating begin, in consequence of which the headache and gastric symptoms largely disappear. The *temperature* usually drops to 100° F. (37.7° C.) by the next morning, to be followed by a new exacerbation of fever, which commences about noon of the second day. The same symptoms now repeat themselves. The affection has usually, by this time, reached its acme, and the temperature may have risen to 106° F. (41.1° C.). Grave *nervous symptoms* may also have appeared. The *urine* is diminished in amount, often slightly albuminous, and acute nephritis is observed in 4.7 per cent. of the cases (Thayer); while either a slight or marked hepatogenous jaundice may appear. A. C. Smith¹ reports instances of bubo (inguinal) as a complication. *Herpes labialis* is quite common. The nocturnal remission again ensues, and in the *mild types* or in those brought promptly under suitable treatment the febrile paroxysms grow briefer, resulting in an intermittent form of fever. The course of light cases is run, usually, within two weeks.

In *severe types* or in neglected cases the separate febrile paroxysms grow longer until the remissions become slight and simulate continued fevers. These are the cases that are distinguished by the same symptoms as those that mark typhoid fever, save only the eruption and the Widal reaction. The course of the attack, if not properly treated, prolongs itself to three, four, or more weeks, and the salient features of pernicious intermittent may suddenly appear and the disease may terminate life. On the other hand, *mild forms* of the continued type also occur, and these yield promptly to the specific—quinin.

¹ *New York Med. Jour.*, June 22, 1901.

(IV.) **Malarial Cachexia.**—This is an exceedingly *chronic* condition, and is usually a remnant of one of the acute forms. When the latter are not properly treated, they are apt to drag on, and assume the characteristic features of chronic malarial cachexia. The condition may, however, be chronic from the start in truly malarial localities.

The **symptoms** are varied both in character and in intensity. There is *fever* at intervals, but chills do not occur, and the temperature-curve is typical neither of remittent nor intermittent fever, although it may approximate either the one or the other. Again, the fever is sometimes wholly irregular, though its range is not high, and it seldom exceeds 103° F. (39.4° C.). The *skin* often presents the dirty yellowish-brown complexion to a marked degree. The spleen is enormously enlarged and indurated, and hypertrophy with hardening of the liver may also be pronounced. The *blood* is profoundly anemic, the count in one of my cases showing but 1,300,000 red corpuscles per cubic millimeter.

Many of the local and general symptoms are dependent upon the well-known *anemia*. Among *general features* may be mentioned debility, frequent sweatings, and dropsy. *Nervous symptoms* may also be noticeable, and chief among these are tremors, neuralgia, palsies, vertigo, wakefulness, and nervous palpitation of the heart. Among the rarest concomitants of this condition is paraplegia. *Malarial neuritis* is met with and presents most of the features common to other toxic forms of neuritis. Slight cough and dyspnea evidence the presence of mild *bronchitis*; and anorexia, nausea, diarrhea, and other symptoms of *chronic gastro-intestinal catarrh* are observed. The joints and voluntary muscles may be painful. *Hemorrhages* from the various mucous surfaces and into the retina are common; and I have seen one case in which spongy, bleeding gums, with numerous petechiæ, pointed to the existence of associated scorbutus. *Tuberculosis* finally developed and carried off the patient. *Chronic dysentery*, *fatty degeneration of the heart*, and *chronic nephritis* may develop and prove serious sequelæ. These cases do well, generally, if the patient can be removed permanently from the malarial district. In long-standing cases the spleen does not return to its natural dimensions. Complete recovery, however, may be expected.

(V.) **Masked Intermittent.**—This presents itself in much the same forms as chronic malarial cachexia, but with the important difference that there is no fever. This type comprises a long list of conditions, at the head of which stands *neuralgia*, most frequently involving the supra-orbital branch of the trigeminus. Often a striking periodicity is observed, the painful paroxysms usually beginning in the morning and terminating in the late afternoon hours, the patient's sufferings increasing steadily in intensity until just before the close of the attack, when they suddenly abate. Among other nerves implicated with relative frequency are the occipital, the intercostal, and the sciatic. Except the blood-appearances be characteristic or unless the attacks yield promptly to quinin, a certain diagnosis of malarial neuralgia should not be ventured. Craig,¹ out of 395 cases of latent and masked malaria, found the estivo-autumnal parasite in 275; they appeared as a small hyaline disc or ring-form within the red blood-corpuscle. The parasites, however, have been observed in all stages of growth, even undergoing segmentation. Craig

¹ *Amer. Med.*, Oct. 29, 1904.

believes that the latency can be accounted for by the fact that the few organisms present do not generate sufficient toxin to provoke characteristic symptoms. These masked cases simulate other conditions, particularly of the alimentary tract and of the lungs. Masked intermittents may assume the forms of paresthesia, anesthesia, convulsions, or paralysis: they may also appear under the guise of edema, hemorrhages from the various mucous outlets of the body or into the skin, intestinal flux (diarrhea, dysentery), dyspepsia, appendicitis, etc. But, since these affections may all obey the law of periodicity, we should not pronounce in favor of malarial infection unless they yield readily to the therapeutic specific, or the parasite is found.

(VI.) **Malarial Hematuria and Hemoglobinuria.**—I have previously described a hemorrhagic form of pernicious intermittent in many cases of which hematuria is a prominent symptom. Boisson,¹ in 3 cases of hemoglobinuric fever, occurring in soldiers attacked with malaria in Madagascar, found great reduction in the erythrocytes, while 7 out of 10 red cells contained parasites. I have observed several instances of malarial hematuria in the Kensington district of Philadelphia, where the milder forms of malaria prevail. Hematuria in its severest form is seen with the approach of cold weather (Jones). It is rare in the negro. Young in both sexes and males over puberty are most apt to suffer. The blood shows pigmented parasites (forming rosettes), and sometimes crescents and pigmented leukocytes.

The **symptoms** consist of a mild cold stage, a subfebrile temperature to which is added hematuria, or more often hemoglobinuria. The paroxysms may recur daily, bi-daily, or at longer intervals, and in severe forms the hemoglobinuria may be continuous, with aggravations at definite intervals. Suppression of urine may appear early, and may be accompanied by nausea, vomiting, and paresis of the bowel, and a semicomatose state, the patient presenting the general picture of uremia. The *diagnosis* demands the demonstration of the malarial parasites in the blood, and of the hemoglobin in the urine. Tyson recommends Teichmann's (hemin crystals) test to show the presence of hemoglobin. The earthy phosphates are precipitated, filtered out, and a small portion placed on a glass slide and carefully warmed until completely dry. A minute granule of common salt is carried on the point of a knife to the dried mass and thoroughly mixed with it. Any excess of salt is then removed, the mixture is covered with a thin glass cover, a hair interposed, and a drop or two of glacial acetic acid allowed to pass under. The slide is then carefully warmed until bubbles begin to make their appearance. After cooling, hemin crystals can be seen by the aid of the microscope, and are easily recognizable by an amplification of 300 diameters. Chemically they are hydrochlorate of hematin.

The so-called blackwater fever is an intoxication due to repeated attacks of malaria, in which "some exciting cause produces a sudden hemolysis" (Prout), which causes quick spontaneous disappearance of the malarial parasites (Plehn). Other observers (Sambon, Macay, and Coulet) regard hemoglobinuria as a specific disease. The leading characteristics are irregular paroxysms of fever with rigor, bilious vomiting, jaundice, hemoglobinuria, and nephritis. This form occurs in the Philippines, in Germany, and other countries.

¹ *Rev. de Méd.*, May 10, 1896.

According to Frank A. Jones, obesity occurs among persons coming from a climate free from malaria to the Mississippi's delta. They neither have chills nor manifestations of chronic malaria. "The obesity subsides rapidly by changing from a malarious to a non-malarious climate."

Complications.—The author's analysis of 1780 cases of malaria (intermittents and remittents) showed complications in about 10 per cent. The more common among these were: Enteritis (16), nephritis (14), rheumatism (10), typhoid fever (8), lobar pneumonia (5), jaundice (5), and dysentery (4). The opinion of the profession is divided upon the question: "Has pneumonia any special connection with malaria?" According to the results of my collective investigations, pneumonia is rarely associated. Craig affirms that malaria may present typical symptoms of pneumonia, probably owing to a localization of the malarial parasite in the capillaries of the lungs. Thayer's studies show that the frequency of albuminuria and nephritis in malarial fever is somewhat below that observed in the more severe acute infections.

Typhoid fever is a complication of malaria, according to these researches, but the relationship between these affections cannot be close.

Diagnosis.—(1) **Of Intermittents.**—This is difficult, unless the brief febrile paroxysms, with their characteristic stages and other diagnostic features (enlarged spleen, malarial complexion, herpes), together with the rigid periodicity of the paroxysms, be present. Residence in a malarial district is confirmatory. The only unquestionable method of diagnosis is provided by a microscopic examination of the fresh blood. If this cannot be made an early diagnosis is rarely possible until the peculiar manner of recurrence of the paroxysms is established.

Differential Diagnosis.—Non-malarial affections, exhibiting an intermittent form of fever, are often mistaken for malarial intermittents. Of these, (a) *pyemia* is very apt to be thus confounded. It will be observed, however, that the chills recur at the more irregular intervals, and that prostration is more profound during the intervals between the febrile exacerbations. The etiologic factors and place of residence are also to be considered. The blood should be examined microscopically, and, if this be impossible, the therapeutic test will, as a rule, remove any doubt. *Leukocytosis* is common in pyemia and absent in malaria.

(b) *Acute tuberculosis* and, more rarely, *incipient chronic tuberculosis* may present a febrile movement in no way differing from quotidian intermittent, except that in the former the pyrexia develops in the afternoon instead of the forenoon, as in the latter. A clear history, the associated local and general symptoms, along with the results of a careful physical examination, usually render tuberculosis probable and distinguish it from malarial intermittents. In tuberculosis the chills recur despite the use of quinin, and this is not the case in malaria.

(c) *Ulcerative endocarditis* may exhibit an intermittent pyrexia, but the history is different, and the associated features are more numerous and decidedly more grave. A blood-examination reveals leukocytosis—a distinguishing feature. Again, quinin is without effect. The irregular forms of intermittents are difficult in the extreme to diagnosticate. If, in suspected cases of "erratic" malaria, quinin is resisted, we cannot feel certain of our diagnosis unless we obtain the microscopic evidence of the presence of the malarial parasite in the blood.

(2) The diagnosis of **remittent fever** would be easily made if it did not sometimes bear a strong resemblance to typhoid fever. Its certain recognition demands the detection in the blood of the estivo-autumnal parasite. In *typhoid fever* the history points to a more gradual onset, the remissions are less marked, and epigastric oppression is wanting. Again, typhoid has its characteristic eruption and gives the sero-reaction. (For diagnosis from hepatic abscess, *vide* p. 922.) Chronic malaria must be differentiated from *chronic biliousness* or *enterogenic intoxication*.

Method of Examining the Blood for the Malarial Parasite.—The finger or lobe of the ear is carefully cleansed, and then slightly cut with a sharp lancet. The first drop of blood is wiped away and the second collected on the center of a clean cover-glass, which is immediately placed upon a clean slide and the blood allowed to spread in a thin film, and examined immediately through an oil-immersion objective. It is all-important that the blood be perfectly spread between the surfaces of the slide and cover-glass, in order that the corpuscles do not rest one against the other. In the fresh specimen one is able to detect the parasite during all its developmental stages seen in man. If the blood of estivo-autumnal fever be exposed to the air a short time and then mounted in this manner, it is likely to display flagella. If desirable to preserve the specimen or if impossible to make the microscopic examination at once, smears should be prepared by laying another cover upon the first, allowing the blood to spread in a thin layer, and then sliding them apart quickly and drying in the air. If permanent specimens are desired, Wright's modification of Romonowski's stain is to be preferred. The specimen should be covered with the solution and allowed to stand two minutes. To stain, add 3 or 4 drops of distilled water and allow to remain two or more minutes, when the specimen is washed with water, dried, and mounted in Canada balsam. The organisms appear as small blue bodies, often containing pigment. For the crescent and oval forms, often difficult to find, it may be advantageous to allow a drop of blood to dry upon the cover-glass without spreading, fix, and then wash with dilute acetic acid; wash thoroughly with water and stain as before. The hemoglobin of the red cells is dissolved, and only the white cells and the parasites remain visible.

Prognosis.—Uncomplicated cases of intermittent fever under proper treatment generally recover. In certain malarious regions and in certain seasons pernicious types are prevalent. *Primary pernicious attacks* are moderately dangerous, while recurrences are highly so. The mortality-rate in this variety is between 20 and 25 per cent.

In *remittent fever* death may be due to asthenia, particularly when the type is severe and when wrong notions as to treatment prevail. Suppression of urine, followed by uremic symptoms, hemorrhages, and intense jaundice are untoward complications.

Treatment.—**Prophylaxis.**—The investigations cited above show that an individual ill of malaria is a source of danger in a community, and should be promptly protected from mosquitoes, and then treated. The homes, and more particularly the sleeping-apartments, of persons residing in paludal regions, should be protected against invasion by mosquitoes. The use of wire netting is to be advised for this purpose. Caps to which the same material is attached may be worn out

of doors. Methods for destroying the mosquito (adult female and larvæ) should be adopted. In rooms this is best accomplished by fumigation; in the outer world the breeding-places (*e. g.*, marshes) must be found and then removed by thorough drainage and covering water-barrels and privies. The larvæ are most effectually suffocated by sprinkling petroleum upon the water, to the surface of which they rise to get air.

Koch states that gametes are often found in children and that many persons harbor the parasite without manifesting active symptoms; he advises prophylactic doses of quinine in malarial localities.

1. For **intermittent malarial fever** there is an almost infallible remedy in quinin. "When shall its use be commenced?" is a pertinent question. It would certainly seem highly desirable to check the course of the disease as soon as possible, and especially since transmission of the simple intermittents into the pernicious forms may occur if the disease be not arrested. At the present day specific treatment is often delayed in order to give full opportunity for making a blood-examination with a view to completing the diagnosis. There is no decided advantage in commencing the use of quinin during the first paroxysm, when the blood may be examined; but on finding the case to be one of malaria, quinin should be administered after the paroxysm, so as to prevent a recurrence. For like reason, if the history at the physician's first visit, combined with the symptoms presented, make the diagnosis of intermittent malaria reasonably certain, and there is no opportunity to examine the blood microscopically, the principal antiperiodic remedy should be commenced at the close of the paroxysm. The quinin cures malaria by acting directly upon the intracorpuscular hematozoa (the young forms).

During the *paroxysm* we should aim to make the patient comfortable. He is to remain in bed, is to be well covered, and external heat applied during the cold stage; and he is to be lightly covered, given cooling drinks and cold spongings during the hot stage.

During the *apyrexial intervals* the patient may leave his bed, provided that he feel strong enough, and, as before intimated, the specific remedy is given during the afebrile period. Certain authors recommend that the entire daily quantity be given at one dose from four to six hours before the succeeding paroxysm is expected, the object being to surcharge the blood at the time when the hematozoa sporulate. The total amount per day required to cut short the intermittents is from 16 to 20 grains (1.036 to 1.296) in most temperate climates. When this fails, more may be given—24 to 30 grains (1.555–1.944). My own practice has been to administer immediately after the close of the sweating stage gr. iv or v (0.259 or 0.324), repeating the same dose a few hours later, and the remaining 8 or 10 grains (0.518 or 0.648) (or one-half the daily dose) six hours before the time for the next paroxysm. I have thus escaped the slight toxic symptoms (tinnitus, deafness, nausea, etc.) which are apt to follow single large doses. The remedy is best given in capsules, followed by a few drops of dilute hydrochloric acid, with a view to dissolving the quinin in the stomach. After the attacks cease to recur quinin should be continued in amounts of 6 to 8 grains (0.388 to 0.518) daily for several days. If quinin cannot be taken *per os* it may be tried by enema or by suppositories in appropriately large doses. In young subjects I administer the quinin by suppository.

The physiologic effects of the drug can be quickly obtained by administering it hypodermically. Hence, if there be no time for absorption from the stomach (four hours being the shortest period it is safe to allow), the drug should be thus employed. For this purpose the more soluble salts (hydrobromate, bihydrochlorate) of quinin are to be preferred to the ordinary and more insoluble sulphate.

Many preparations of cinchona other than the salts of quinin may be tried, and among these cinchonin administered in the same manner as the latter is the best substitute. Some contend that the sulphate of quinidin has antiperiodic power, almost equal to quinin. In prolonged cases the salts of quinin and other preparations of cinchona sometimes lose their specific influence, and arsenic is then to be employed, either alone or in combination with the former agents. The dose of the arsenic, beginning with $\mathfrak{M}\text{iv}$ (0.266) t. i. d. of Fowler's solution, must be increased until its physiologic effects are produced. Arsenious acid often does even better service than Fowler's solution. Administered as above indicated, this remedy is most efficacious in malarial cachexia and masked forms of intermittents; it may be combined with iron and quinin. Atoxyl, either alone or associated with quinin, is capable of bringing about rapid improvement in health, especially in cachexia and chronic forms of malaria. In cases of malaria that are resistant to quinin (often the quotidian forms), methylene-blue has been found extremely active and serviceable. Cardamates believes that it is indicated only when quinin is contraindicated, as in hemoglobinuria or in pregnancy, when abortion is feared. It attacks the adult forms of the parasite. Werner recommends "606" (0.6 to 0.7 gram) in cases in which the parasite is resistant to quinin. While in charge of the out-patient service of the Episcopal Hospital, Philadelphia, I employed in chronic malarial cachexia, with very satisfactory results, the sulphate of cinchonidin in daily doses of gr. xxx-xl (1.944-2.592). In this class of cases Warburg's tincture 3ss (16.0), three times a day, has been warmly recommended. Splenectomy has been recommended in intractable forms, but it is to be performed only as a *dernier ressort*.

2. **The Treatment of Pernicious Intermittents.**—(a) *Prophylaxis.*—By treating all ordinary intermittents actively after the first paroxysms the occurrence of pernicious forms can be obviated. Not to pursue this course in malarial seasons and localities is next to criminal.

(b) *The first pernicious attack* must be treated immediately, and there is not a moment to be lost. Hence in all varieties of pernicious intermittents quinin should be administered hypodermically until the patient is fully cinchonized—a condition that must then be maintained for several days. In all varieties stimulants are to be used freely if the heart's action becomes feeble, and the patient is to be well nourished throughout. There are other details, though of relatively minor importance, and they vary with the individual forms. Thus in "congestive chills" external warmth is useful, and morphin combined with atropin should be given hypodermically, this combination tending to allay gastro-intestinal symptoms as well as to warm the extremities, and meeting really important indications. Rectal feeding must be resorted to should the stomach refuse to retain nourishment. In the *comatose form* the nervous symptoms are most successfully combated by prompt and energetic

antiperiodic treatment, together with vigorous stimulation and feeding, since they are due to the intensity of the infectious process.

(c) During the apyrexial period every effort must be made to prevent a recurrence of the paroxysm, and to this end the patient must be kept fully cinchonized until the time for the next paroxysm is over.

3. Treatment of Remittent Fever.—The mode of treatment in this form differs somewhat from that appropriate for intermittents. At the onset a mild mercurial is advantageous (calomel gr. $\frac{1}{4}$ (0.0162) every hour for three doses), followed by a saline laxative (Rochelle salts, 3ij; 8.0). During the febrile exacerbations cool spongings of the body, coupled with the use of the ice-cap, are serviceable. The gastric symptoms demand chipped ice by the mouth or small doses of cocain, and a mustard plaster externally. Immediately after the first remission sets in quinin must be exhibited, and large doses are now indicated (gr. xv (0.972), to be repeated at 8 or 9 A. M.). A third and even a fourth dose of the same size may be required. The exacerbations of fever generally yield to this remedy, but if, as rarely happens, they do not, then small doses of pilocarpin (gr. $\frac{1}{8}$ to $\frac{1}{6}$; 0.008 to 0.010) may be administered hypodermically during the height of the fever. This causes free sweating in many instances, and in consequence renders the remission more marked and more prolonged; thus, in short, rendering the course of the affection speedily favorable. The heart must be guarded.

A case that has been allowed to run on for one, two, or more weeks is often greatly benefited by the use of Warburg's tincture, as before recommended, for several days, when quinin may be re-employed. The patient, especially if the case be protracted, must be vigorously fed, and *per rectum* if it cannot be accomplished by the mouth. In typical cases, which are promptly controlled by quinin, stimulants are rarely needed, or at least not until the convalescent stage is arrived at. In severe and neglected cases the indications for their employment may be presented early, and they should then be given, the physician conforming to the same rules as in typhoid and other acute infectious diseases. The renal congestion and anuria are to be met by internal diaphoretics (pilocarpin, etc.) and by saline laxatives. Most efficacious, perhaps, is a combined hot-water and steam bath. The patient is placed in hot water, and then a blanket is put around the neck, its free ends being allowed to extend over the edges of the tub.

4. Treatment of Malarial Hematuria.—Whether or not quinin is to be employed in hemorrhagic pernicious malaria is a question involved in doubt. The statistics of M. Brady indicate a tremendous advantage in discontinuing quinin as soon as blood shows in the urine—a reduction of mortality from 24 to 6 per cent. Forcheimer also holds that if in an attack of black-water fever the administration of quinin is followed by hemoglobinuria, the quinin should be withheld. Under these circumstances the use of methylene-blue has given favorable results. This remedy is best administered in doses of gr. iss-iiss (0.097–0.162) every third hour, and it should be continued in somewhat diminished dosage for a week or longer after the cessation of fever.

DISTOMIASIS.

(Trematodiasis.)

VARIOUS forms of trematodes, including the distomata, may become parasitic in man.

Distoma Hepaticum (Liver-fluke).—Among the more common varieties of trematodes or flukes, is the distoma hepaticum or liver-fluke, a parasite found in animals (horse, goat, ass, sheep, rabbit) and accidentally ingested by man.

It is almost 30 millimeters (1.1 inches) in length, and inhabits the biliary passages of the animal, and from them is discharged into the intestinal tract and evacuated with the feces. Under certain conditions of temperature and moisture, a ciliated embryo escapes from the egg, and is ingested by a gasteropod or snail (*limnæa truncatula*), in which it undergoes development into a sporocyst, that in turn gives origin to *radix* or parent nurses. These give birth to daughter-radix or *cercariæ*, which leave the gasteropod or snail and attach themselves to aquatic plants, where they are in turn eaten by animals.

Symptoms.—When present in sufficient numbers in the bile-passages the liver becomes greatly enlarged, with the occurrence of jaundice and ascites that may prove fatal. Other symptoms may also be present; thus pain was prominent in 41 out of 100 cases reported by Kurimato in Japan, and heart-murmurs were present in 42 of those cases.

Late in the disease the liver may become nodulated and terminate in atrophy.

On inspection in well-marked cases, a peculiar barrel-shaped bulging is sometimes seen, extending over the hepatic area, with tense abdominal walls over the enlarged liver. This is a pathognomonic symptom of hepatic distoma. An endemic form occurring in Japan has been described; it is characterized by marked emaciation, diarrhea, hepatic enlargement, and often by ascites.

The **prognosis** of distoma hepaticum is absolutely fatal and the **treatment** is merely palliative, though it may run a course extending through many years, often with intermissions, even apparent recovery, later to relapse.

Among other trematodes may be mentioned (a) *distoma lanceolatum* (found also in cattle); (b) *distoma crassum*, which is larger in size than the preceding; (c) *distoma sibiricum*; (d) *distoma pulmonale* (*D. Ringeri*); (e) *distoma spatulatum* (*endemicum*); (f) *amphistomum hominis*; (g) *distoma hematobium* (Bilharz). Two of these deserve extra, though brief, mention.

Parasitic Hemoptysis (*Distoma Pulmonale*).—This is caused by the *Paragonimus Westermanii* first described by Manson (1880) and Baily (1880) in man. The lung fluke worm has also been found in the tiger (originally by Kerbert), hog, dog, and cat. The disease is extremely prevalent in certain provinces of Japan and China. Elsewhere it is usually mistaken for pulmonary tuberculosis. Stiles and Hassall¹ have discussed the whole subject. The parasite is 8 to 16 mm. long, 4 to 6 mm. broad, and 2 to 5 mm. thick. It is found encysted,

¹ *Annual Report of the Bureau of Animal Industry*, 1899.

usually two individuals in each cyst, with eggs, and its habitat is the lungs of mammals. It enters its final host (man, etc.) either encysted or as a free-swimming *cercaria*. *The mode of infection*.—Eastern writers look upon the drinking-water supply as the source of infection, and this view has much in its favor. The disease has been found in hogs throughout various sections of the United States by Stiles; this suggests the possibility of widespread infection in America.

Predisposition.—Most cases occur between the ages of eleven and thirty years. Out of 58 sufferers, 38 were farmers (Stiles).

Symptoms.—In the usual form (lung infection), *cough* is common but not constant; the sputa are similar to those of lobar pneumonia, although they may be absent from time to time. Free *blood-spitting* often occurs at intervals. Jacksonian epilepsy may supervene from metastasis to the brain.

Diagnosis.—This rests upon the detection of the eggs in the sputum. Place a drop of the bloody sputum on a slide, and upon it a cover-glass. On microscopic examination the red color will be found due to both red blood-cells and large dark-brown, thick-shelled, operculated ova, which vary from 80 to 100 μ in length, and from 40 to 60 μ in breadth.

The **prognosis** depends upon the number of the *parasites present*, the *age of the patient* (the young and the old bearing the disease badly) and the presence or absence of complications. Pulmonary tuberculosis is an unfavorable complication.

Treatment.—Prophylaxis embraces care regarding the drinking-water, and the collection and disinfection of the sputum as in pulmonary tuberculosis. The patient should be sent to healthy non-infected areas. There is no special *medical* treatment.

Distoma Hematobium (*Bilharzia hematobia*; *Blood-flukes*).—This hematozoa is a narrow worm with anterior abdominal sucking-disks. The male is shorter and thicker than the female; the former being 4–15 mm. ($\frac{1}{6}$ – $\frac{3}{8}$ in.) long; the latter, about 20 mm. ($\frac{4}{5}$ in.). It prevails mostly in Egypt, Cape Colony, and other parts of Africa, and its entrance into the human body is now believed to be through the skin of those who bathe frequently in the African rivers, in many of which it abounds. It is not unlikely that, as formerly held, infection may also occur in many cases from drinking the impure water of the rivers. The parasites or their ova are found in the bladder, the pelvis of the kidney, and the veins (portal, mesenteric), most rarely the pulmonary.

The **symptoms** are hematuria, with some pain during urination. The last few drops of urine voided only contain blood, although rarely hemorrhage is more extensive and then the entire bulk is blood-tinged. Cystitis often occurs, with resultant thickening of the bladder wall. The ova become nuclei for vesical stone-formation.

Proctitis may result when the parasites lodge in the rectum, in which case mucous and bloody stools with tenesmus result. Ova of the parasites are found in the urine. No serious systematic disturbances occur in bilharziosis. Prophylaxis as regards drinking and bathing in African waters should be exercised. Fouquet affirms the value of the extract of male fern internally in this form of distomiasis.

CESTODES.

ECHINOCOCCUS DISEASE.

(Hydatid or Bladder-worm Disease.)

THE *tænia echinococcus* is the smallest tape-worm of our domestic animals, and lives between the villi in the small intestine, especially in the larger breeds of dogs. It has a length of from 4 to 9 mm. ($\frac{1}{5}$ to $\frac{1}{3}$ in.), and consists of only three or four sections, the last one of which is mature. The rostellum projecting from the small head has thirty or forty hooklets arranged in a double row and a quadruple sucking apparatus. Thousands of eggs are contained in the mature segment. The intermediary hosts for the larvæ are rarely man, the horse, and the sheep, but more often the hog and ox.

Life History.—The ova, embryos, or the proglottides even, of the adult tenia are voided by the dog, and in various ways, later, are ingested by man. The dog first becomes infected by eating the echinococcus cysts of some animal that harbors the larval form of the tenia, and the matured teniæ appear in from eight to ten weeks. The liberated six-hooked embryos burrow through the intestinal wall or enter the portal vein; they pass into the solid viscera and muscles. There they develop into the larval form and cause the formation of echinococcus cysts.

In the development of echinococcus cysts, about four weeks after the ingestion of the bladder-worm eggs, small nodules appear, about 1 mm. ($\frac{1}{25}$ in.) in size. In about five months the cyst-walls consist of two layers, an external layer and an inner, granular, parenchymatous layer (or endocyst), containing a clear liquid. As the reaction to the irritation caused by the parasite and its cyst increases, a fibrous investment forms around them. At this time, also, small daughter-cysts, or vesicular buds, form the minor granular layer of the mother-cyst, and contain the heads of the larvæ. They are soon set free, and may themselves give rise to other or granddaughter-cysts in a similar way. These really become the breeding capsules of little cellular outgrowths that form the scolices or heads of future teniæ. They show the four sucking disks and a circle of hooklets. Each scolex, when taken into the intestine of the dog, develops into an adult bladder-worm or *tænia echinococcus*. This endogenous mode of cystic growth is common in man (*E. hydatidosus*). In animals the so-called exogenous cyst development is the more common in which the primary cyst-buds push out between the cyst wall and then develop externally. A third variety is the multilocular echinococcus (*E. alveolaris*, Buhl), affecting principally the liver. A large, hard tumor is seen that on section shows a firm connective-tissue framework surrounding alveoli that average a small pea in size. These alveoli contain small echinococcus cysts with thick, laminated walls. They may contain scolices or hooklets, and sometimes they are sterile. The echinococci may be situated in the lymph-channels and bile-ducts (Zenker).

The pure hydatid fluid is colorless, limpid, neutral in reaction, and has a specific gravity of 1005 to 1012. About 96 to 98 per cent. is water, and sodium chlorid, carbonate, and sulphate; traces of sugar (dextrose); cholesterin and uric acid are found among the constituents.

Among the changes that an echinococcus cyst may undergo the commonest is that of the death of the echinococci, as from diminished nourishment due to intense proliferation of daughter- and granddaughter-

cysts. The contents become thickened, putty-like, or granular, and even calcified. Remnants of these obsolete cysts, such as the chitinous substance of the old and outer wall-layer and hooklets, may be found. Sometimes *rupture* of the cyst occurs, with serious consequences to the patient; or the peritoneum daughter-cysts or free scolices may be disseminated and grow. Or *perforation* into the respiratory, digestive, or urinary tracts and discharge of daughter-cysts and hydatid fluid may take place. Lastly, *suppuration* and the formation of large hepatic abscesses may ensue, either spontaneously or on account of septic instruments used for tapping the cysts.

Etiology.—Carelessness in the feeding and the keeping of dogs is the primary source of hydatid disease, and the preparing of food where dogs are allowed to roam about, and so on, accounts for the majority of cases. Females are more often affected than males, and children and young adults seem to be oftener affected than those older in years.

As regards the *geographic distribution*, echinococcus disease prevails most extensively in Iceland, where man and dog live closely together. In Australia, also, many persons are affected. It is not so common in Europe, Asia, or Africa, and in America it is rare.

Organs Affected.—The *tenia echinococcus* has an undoubted predilection for the liver. "Of 1806 organ-infections, the following organs were the most frequently affected: liver (1011), lung (147), and kidney (126)" (Stiles). The brain and spinal cord, spleen, bones, muscles, the heart, and blood-vessels are involved with uncertain frequency.

Symptoms.—**Hydatids of the Liver.**—Unless the cystic tumors compress the portal area or the biliary passages, or invade the neighboring viscera, subjective symptoms may be entirely wanting. Not infrequently echinococcus sacs, partly calcified, have been found *postmortem*, not having produced any symptoms during life. Gradual but progressive loss of flesh and strength with the presence of a fluctuating tumor may be the only symptoms present until late in the disease. If the cysts attain a large size, a sensation of dragging, and of pain even, is often present; as a rule, however, pain is absent throughout the course of the disease. If the tumor displaces the diaphragm upward and compresses the lung, cough and dyspnea result. In some cases the sac has ruptured into the bronchi, and given rise to cough and to expectoration of the fluid and vesicles.

If the portal veins and bile-duct are compressed, splenic enlargement from passive congestion, ascites, and jaundice will occur, these symptoms being more common when the cysts are multilocular. Rupture may occur into the intestines (colon), into the pleura or pericardium, causing pyothorax or pyo-pericardium, or into the inferior vena cava, causing fatal pulmonary embolism.

Fever is usually absent throughout, unless the contents of the sac become converted into an abscess; then rigors or chills, fever (hectic in type), and sweatings occur, with jaundice (more or less intense) and rapid emaciation.

Not infrequently the cyst-wall becomes partly calcified and the contents are reabsorbed.

When rupture occurs, unless the contents be evacuated through the respiratory, alimentary, or urinary tracts or externally, symptoms of collapse develop and are followed by death. Toxic erythema or urticaria may follow rupture of cyst.

The **physical signs** give on *inspection* fullness or bulging in the right

hypochondriac region, especially if the cyst be single, of large size, and situated anteriorly.

Palpation confirms inspection and shows a fluctuating mass or masses. A trembling impulse is felt sometimes on deep palpation, aided by light percussion over the opposite side of the cyst, constituting the so-called "hydatid thrill." This sign cannot always be elicited, but when present is pathognomonic of the disease. The remainder of the liver shows uniform enlargement. The spleen is often palpably increased in size from passive congestion.

Percussion reveals, in addition to the hydatid fremitus, an increased area of dulness to the left or posteriorly, depending on the location and extent of the growths. If the left lobe be involved, the line of flatness may extend across the sternum to the left hypochondriac region. If the cysts are multiple and on the antero-inferior surface, the stomach may be displaced toward the left and dulness may extend across the epigastrium; if posteriorly, the pleural cavity may be encroached upon, causing an increased area of flatness upward in the postero-axillary line. Frerichs claims the line of dulness posteriorly in hydatid disease to be a curved one, whose convexity is upward.

Auscultation gives, according to Santoni and others, a short sharp booming sound when the tumor is percussed, that may be likened to one produced by striking a membrane stretched over a metallic frame.

Diagnosis.—In the entire absence of subjective symptoms and of characteristic physical signs, the diagnosis is impossible. If the cyst be of sufficient size to give fluctuation and the liver be irregularly enlarged, with an absence of fever, pain, and marked emaciation, the disease may be strongly suspected. The only certain demonstration of the condition is the discovery of the characteristic hooklets or heads in the aspirated or discharging contents of the cyst. Among the conditions that may be misdiagnosed for hydatid disease are—(a) Dilatation of the gall-bladder, (b) hydronephrosis, (c) right-sided pleurisy with effusion, (d) syphilis of the liver, (e) carcinoma, (f) abscess, and (g) cirrhosis.

HYDATID CYST.

Previous history negative, except the companionship of dogs.
Pain and jaundice usually absent.

Enlargement in any direction, depending upon the location of the cysts.
Hydatid thrill may be present.
Less so.

HYDATID CYST.

The history is negative (*vide supra*).
Urinalysis is negative.

The tumor is most prominent over the hepatic area, and is associated with enlargement of the liver.

The duration is indefinite and uremia rare.

DILATATION OF THE GALL-BLADDER.

A previous history of having passed biliary calculi is often present.

Attacks of biliary colic followed by jaundice either are present or enter into the previous history.

Enlargement is always in one direction—downward and posteriorly.

"Hydatid fremitus" never present.

The tumor is somewhat movable.

HYDRONEPHROSIS.

There is a history of renal calculi or of vesical inflammation.

Urinalysis reveals evidences of renal disease.

The tumor is most prominent in the flank and iliac fossa. If extending to the right hypochondriac region, it *does not* move with the liver.

The duration is short; a termination in uremia is common.

HYDATID CYST.

The onset is slow; pain and fever are absent.

The presence of a fluctuating mass in the hepatic area, *not changing with the position of the patient*. Hydatid fremitus is present, but no bulging of the intercostal spaces.

Aspiration reveals a clear yellow liquid of low specific gravity without albumin, but chlorids, sugar, and hooklets.

The disease invariably runs a chronic course.

PLEURISY WITH EFFUSION.

The onset is sudden, and violent pain is present, with fever and dyspnea.

The presence of effusion, beginning at the base of the chest and gradually extending upward—*changing with the position of the patient* and accompanied by bulging of the intercostal spaces.

Aspiration gives a cloudy, turbid liquid, containing albumin and flakes of lymph with high specific gravity.

The disease generally runs an acute course.

For a differential diagnosis from (*d*), (*e*), (*f*), and (*g*) I would refer the reader to the discussion of the several diseases (*vide* Diseases of the Liver).

Echinococcus of the Respiratory Organs.—The lung has been the seat of the larvæ quite frequently, and instances have been noted especially in North Germany and Australia. The right lower lobe has been the seat of predilection, though sometimes the pleura is the primary source of trouble. There are pain in the chest, cough, dyspnea, perhaps arching of the overhanging thoracic region, signs of a pleural effusion, a tympanitic note above the prominence, hemoptysis, and the pathognomonic expectoration of hydatid disease. The general condition may not be seriously affected. Perforation into the pleural sac by pulmonary echinococci may be followed by empyema, and, later, by perforation of the chest wall. The heart may be dislocated. Compression of the lung may produce gangrene.

The *diagnosis*, in the absence of the characteristic sputum, is to be made from phthisis and a pleural effusion. Their location at the base of the chest may serve to differentiate hydatid cysts from phthisis, as well as the absence of marked emaciation. The characteristic curved upper boundary of dulness in pleural effusion and the change of the boundary upon changing the patient's position will serve to distinguish this affection. Pleural echinococci sometimes cause great compression of the lung and a barrelling of the chest on one or both sides. The pain may be quite sharp, and the respiratory murmur either distant or altogether absent.

Echinococcus of the Mediastinum.—Hare has collected 6 cases of hydatid disease among 520 cases of mediastinal tumors.

Echinococcus of the Heart.—Most of the cases have shown involvement principally of the right side of the heart.

Echinococcus of the brain and spinal cord should not be confounded with cystic degeneration of the choroid plexuses. J. H. Lloyd found 19 distinct cysts in the lateral ventricles and one occupying the fourth ventricle. The symptoms of cerebral hydatids are those of tumor, persistent and intense cephalalgia, vomiting, psychological disturbances, convulsions, amblyopia, and "choked disk," and sometimes paralysis. Hydatid disease may develop inside the dura mater, or it may penetrate from without and destroy the vertebræ before they compress the cord to a great degree. The symptoms are those of a compression myelitis.

Echinococcus of the Spleen.—About 40 cases of involvement of the spleen have been described. The organ may become greatly enlarged and be mistaken for that due to malaria, leukemia, etc. The hydatid thrill may be detected.

Echinococcus of the Kidneys.—More than 100 cases have been observed, mostly in Germany and France. The cyst may be as large as in hydronephrosis. Many of the cysts are of the exogenous form of growth. As a rule, one kidney only is affected, and generally the left one. Abdominal and thoracic compression symptoms may be caused, and bulging is often present in the lumbar region in marked cases. This may be punctured as an aid in the diagnosis. Rupture into the pelvis of the kidney and the discharge of the smaller cysts may give rise to renal colic and to the discharge of the cysts with the urine. More rarely, rupture of a suppurating cyst may take place in the loin.

Echinococcus of the peritoneum is rare as a primary condition. Echinococci have also been located in the bladder, prostate, testicle, ovary, uterus, great omentum, mesentery, pancreas, arteries, lymphatics, thyroid gland, muscles, bones, joints, parotid gland, orbit, and mamma.

A peculiar **complication** of echinococcus cysts is the occasional development of urticaria. It has been noted especially shortly after the puncture of a cyst, and this is somewhat diagnostic when it appears.

The **prognosis** is generally grave both as to life and cure, although some cases of hydatid disease of the liver have lasted for more than ten years.

The character of the changes in the cysts and their mode of termination influence the prognosis. Thus, the occurrence of suppuration is to be dreaded. Spontaneous cures have been noted in a few instances.

Treatment.—As in most of the other parasitic diseases, prevention is more or less effectual, and a cure is difficult or impossible. Infection of the dog should be avoided by preventing its gaining access to possible sources of hydatid disease, as the raw flesh of animals, especially in the form of meat-scraps around slaughter-houses. In order that human beings may not be affected, dogs should not be carelessly handled or allowed to be where they may come in contact with food and drink in any way, whether meat or eggs, vegetables, fruits, or cereals. Cleanliness in keeping dogs and in the proper preparation of food are essential in regions where hydatid disease is prevalent.

Medicines cannot reach the parasites in man, situated as they are in larval form encysted in the various tissues and organs of the body. Whenever the cyst becomes large, accessible, and the cause of troublesome symptoms, surgical measures may be resorted to. Among these are, simple tapping, tapping with aspiration, and with the subsequent injection of various substances (as iodine and zinc-chloride electrolysis), and incision with drainage. Excision of the liver cysts has been practised by Raggi, Pozzi, Tansini, and others, but its practical value is still undetermined. Should suppuration occur, treat as an abscess.

TENIÆ OR TAPE-WORMS.

Natural History.—Tape-worms are found in the intestine of man, and are the matured or completely developed larvæ or cysticerci from the muscles and solid viscera of animals. Different varieties of cysticerci develop from the ova of the respective varieties of teniæ. These tape-worm eggs, after having passed out of the bowel, may be taken into the systems of various animals by various modes, entering the circulation, it may be, and becoming fixed within the solid tissues, especially the muscles. In about two or three months pea-sized cysts develop, and from the cyst-walls there gradually forms a new tenia-head, called a

scolex, or nurse. The worm-cysts, popularly termed "measles," constitute the cysticeri. Remaining in the tissues, they die and become calcified in from three to six years (Strümpell). But, if taken into the stomach by the eating of raw or partially-cooked meat, a tape-worm develops from the scolex. The maturation of the segments of the tape-worm commences several months after the fixation of the scolex in the intestine. In the natural life-cycle of a tape-worm the usual order of lodgement may be reversed. Thus man instead of a lower animal may become the host of the tenia eggs, which in turn may find their way into the solid viscera and muscles to develop into cysticeri. Again, this same order may be brought about by "auto-infection." The tape-worm has a ribbon-like form; although it has a number of segments and joints, giving it a link-belt appearance. When matured, these segments, or *proglottides*, develop male and female generative organs.

Varieties.—*Tænia Solium* (*Pork Tape-worm*).—This worm is rarer in America and also in Europe than formerly. It develops in the small intestine after the ingestion of raw or underdone "measly" pork. This worm does not necessarily exist singly, as its name would indicate, although such is usually the case. It ranges from 2 to 4 meters (6 to 13 feet) in length. The head is rounded, pin-head in size, and is succeeded by a thread-like neck and by gradually shortening and widening segments. Four suckers and a projecting circle of twenty-six long and short hooklets arm the head of the tenia. The mature ones become detached, and are passed with the feces. They are about 1 centimeter ($\frac{2}{5}$ in.) in length and from 6 to 8 millimeters ($\frac{1}{4}$ – $\frac{1}{3}$ in.) in breadth, and about 1 meter (39.36 in.) from the head they are "approximately quadrilateral" in shape. These proglottides are bisexual. The female matrix occupies the middle of each proglottis, and is provided with from eight to fourteen irregular, tree-like branches on each side. The male generative organs are small vesicles in the anterior portion of the segment. The sexual opening is situated on one side, near the middle. The ovarian or uterine apparatus of a mature segment contains myriads of thick-shelled eggs, each one of which has an embryo with six hooklets.

Tænia Mediocanellata (*Saginata*).—The beef tape-worm is sometimes called the "unarmed tape-worm," since the head possesses sucking disks, but no hooklets. It is more common in this country and even in some of the European countries, as England. Longer than the tenia solium, being 4 to 10 meters (12 to 30 feet) in length, its segments are also thicker and larger, measuring from 16 to 88 mm. ($\frac{2}{3}$ in.) long, and from 8 to 10 mm. ($\frac{1}{3}$ in.) broad. The head of the worm as well as the ripe ovum is also slightly larger and proportionately thicker. The ovarian branches are more numerous (eighteen to thirty in number) and divide more dichotomously than those of tenia solium. Proglottides are also found in the stools, where they sometimes exhibit a crawling motion that has caused them to be mistaken for individual parasites. *Cysticercus saginata* has never been observed in man.

Bothriocephalus latus (*Fish tape-worm, Tænia lata*) occurs most commonly in Russia, Switzerland, Holland, and the German Baltic provinces. It is the longest cestode, measuring from 6 to 10 meters (20 to 30 feet). The head is club-shaped, unarmed, and has two lateral longitudinal grooves as suckers. The segments may be distinguished from

those of the preceding varieties named by their marked breadth and shortness, also by the centrally situated, tortuous ovarian rosette, and the sexual orifice near the center of the abdominal surface of each proglottis. The ova are larger than those of the pork and beef tape-worms, though thinner-shelled and with a sort of lid at one end. They develop only in fresh water. From them is formed an embryo with vibrating cilia and six hooklets. Pike and other fish swallow these embryos, which develop into cysticerci in the muscles, peritoneum, and solid viscera. The eating of measly fish, raw or partially cooked, thus favors the development of this tape-worm in the human intestine.

Symptoms.—Tape-worms may develop in man at any period of life. D. J. Milton Miller met with one in a child a few months old who had been fed on expressed beef-juice. Contrary to what has been supposed in days gone by, there are no absolutely diagnostic symptoms of the presence of tape-worm that can be relied upon. Indeed, the existence of a tape-worm in the bowel may not be suspected even because of the total absence of indicative, subjective sensations. On the other hand, teniæ may cause considerable local distress and impairment of the general health. Because of this fact a knowledge of the existence of tape-worm in certain neurotic subjects leads to an inordinate description of symptoms that exist mainly in the workings of a morbid imagination.

Alimentary symptoms of tape-worm may be as follows: **anorexia** alternating with a voracious appetite, constipation alternating with diarrhea, colicky pains in the abdomen, indigestion, nausea, and vomiting. Certain foods (herring, garlic, sour foods) increase the colic-like pains, others decrease them, as milk, eggs, and oils.

General symptoms of the teniæ may be added, as lassitude, inappetence, mental uneasiness, worry and irritability, depression of spirits, some physical prostration, and even emaciation. Various *reflex symptoms*, such as pruritus of the nose and anus, vertigo, migrain, tinnitus aurium, palpitation, visual disturbances (even temporary amaurosis), unequally dilated pupils, chorea, and epileptiform convulsions have been attributed to these parasites. But, on careful inquiry, adequate causes for some of these symptoms may be found in other associated morbid conditions. The bothriocephalus, however, may cause anemia, often very grave, even fatal. The blood-picture, in fact, is identical with that of pernicious anemia, as Schaumann's study of 38 cases has shown, and as was the case in three Finnish sailors seen by W. E. Robertson. This, in all likelihood, is due to some toxin elaborated by the worm. The blood-findings are otherwise unique among the verminous parasitic diseases in that they are the only class in which eosinophilia does not occur.

Diagnosis.—This is always to be made by the discovery of tenia segments or ova in the underclothing or stools. The doubtful presence of suspected tape-worm may be cleared by the administration of a suitable purgative, which will usually suffice to bring away portions of the worm in the defections. I would here add a special warning lest mucous casts or shreds or vegetable structures (as of onion) be mistaken for tape-worm.

The diagnosis of the variety of the tape-worm is made by a careful scrutiny of the segments. Those of the tenia saginata are larger and fatter than, and their generative apparatus is unlike that, of tenia solium.

Hypochondriasis can be excluded by repeated examinations of the

stools, especially after the exhibition of cathartics, and by the uniform failure to detect portions of tape-worm or tenia eggs.

Prognosis is favorable. Indeed, *tenia saginata* may exist at all ages and for years without any danger to the patient. *Tenia solium*, however, is attended with danger on account of the possibility of its causing cysticercosis.

Treatment.—*Prophylaxis.*—The way to avoid acquiring a tape-worm is to use none but well-cooked meats; this applies to beef and pork in particular. The use of pure drinking-water is of no little importance also. The proglottides of the tenia should always be burned, and not thrown where they may be taken into the bodies of other animals, as the cow or hog, and then be allowed to propagate. Governmental inspection of the meat-supply in abattoirs should be rigidly enforced.

Curative.—Before administering the chosen anthelmintic, the patient needs to undergo a “preparatory treatment.” This has for its object the starvation of the parasite, so as to weaken its hold upon the intestinal mucosa. This is specially necessary in the case of *tania solium*, in which the cephalic hooklets are obstinately and firmly fixed to the membrane, and since a cure cannot be said to have been effected unless the head be dislodged with the dejecta. For about two days prior to giving the remedy the patient should be restricted in diet to milk, light soups, a little white bread, and the like. Meanwhile, the bowels should be purged gently once or twice, after a simple enema.

In the evening preceding the day on which the drug is to be exhibited, a saline cathartic should be given to empty the bowel as completely as possible. The following morning no breakfast should be allowed, and before noon the selected anthelmintic should be administered. If the worm does not come away in a few hours, and an intense sense of pressure is felt in the abdomen, a brisk purge is indicated. The worm should be passed into a bowl containing warm water.

There are several very efficacious anthelmintic drugs to choose from. Prominent among them is male fern. Given to an adult in doses of $\frac{1}{2}$ to 1 dram (2.0–4.0) of the ethereal extract, and followed in several hours by a calomel and a saline purge, it usually succeeds in bringing away the tenia. Schilling gives in the morning, fifteen minutes after a breakfast of coffee with Zweiback, this formula:

| | | |
|-----|--------------------------------------|--------------|
| R̄. | Fresh ethereal extract of male fern, | 3ij ; |
| | Powdered jella, | gr viiss ; |
| | Simple syrup, | q. s. ad 3j. |

Sig. Shake well and take at one dose.

If evacuation of the bowels be delayed, an enema of warm water is indicated. Another valuable remedy is pelletierin, the active principle of pomegranate; the tannate may be prescribed, dose 1 to 1.5 gm., in capsules; or, a decoction of the pomegranate bark may be used, in combination with male fern, as in the Leipsic formula (Strümpell):

| | | |
|---|----------------------------|----------------------|
| R̄. | Granati radiceis corticis, | 3iv–v (128.0–160.0); |
| | Aquæ, | Oij (1 liter). |
| Mix and macerate for twenty-four hours, | | |
| and boil until reduced to | f 3v (148.0). | |
| Add: Oleoresinæ aspidii, | 3j (4.0). | |

Sig. To be taken in three or four doses, at short intervals.

Pepo in emulsion or in a sugary paste (about two ounces—64.0—and deprived of the envelopes) is at once a useful and harmless remedy.

Another effective vermifuge is koussou (*Brayera anthelmintica*). An infusion of half an ounce (16.0) of the flowers to one pint of water and mucilage of acacia is made, a wineglassful of which may be taken every half hour. The Germans recommend sometimes the agreeable, though more expensive, Rosenthal's "koussou tablets." Enough of these to make 15 grains (0.972) may be taken within one hour, with *café noir* or lemonade. Koussin (the active principle) in doses of 30 to 40 grains (1.94–2.592) has also been recommended, but should not be given to pregnant women, as abortion may be produced. Among other remedies of value as vermifuges may be mentioned kamala (1 to 3 drams—4.0–12.0—of the powder and hairs, in wine or water), oil of turpentine ($\frac{1}{2}$ to 2 ounces—16.0–64.0—in emulsion or milk), and thymol. The combined use of such drastics as croton oil renders the action of the anthelmintic drug more certain at times.

Although the head of the tenia may not be detected in the stools along with the body of the worm (and such is usually the case), a cure usually follows nevertheless, since, on account of its smallness, it may easily escape notice, and also from the fact that the head often dies and thus loses its hold upon the membrane, being carried away with the feces. On the other hand, if after the lapse of several months from the removal of a tape-worm, segments again appear in the stools, it may be inferred that the head was not dislodged or that another worm has developed. In cases where the tenia seems to redevelop with remarkable frequency and obstinacy it may happen that the head and neck are well protected beneath one of the valvulæ conniventes.

After the removal of the tape-worm—a weakening procedure, as a rule—the condition calls for supportive measures. The diet should not be too heavy for a time, but nutritious and easily digestible.

TÆNIA NANA.

This is the smallest tape-worm in man (v. Siebold). It varies from 8 to 20 mm. ($\frac{1}{3}$ – $\frac{4}{5}$ in.) in length and from 0.5 to 0.7 mm. ($\frac{1}{50}$ in.) in width. The head has four suckers, a rostellum, and hooklets. The segments are yellowish, short, and broad. It is more common than is supposed. It is believed by some observers that, occurring in children, as it commonly does, this parasite is the cause of *epileptiform convulsions* and *enuresis nocturna*. Thousands of worms may be found within a cubic centimeter of fecal matter. *Hymenolepis nana fraterna*, which develops in rats without intermediate host, is regarded as being identical with the *T. nana*. Persons infected should occupy separate beds until cured. Male fern is the only remedy which has thus far been useful in expelling this worm (Stiles).

TÆNIA FLAVOPUNCTATA.

(*Tenia Diminuta*; *Tenia Leptocephalata*.)

Tænia diminuta is a very small cestode, 20 to 60 mm. ($\frac{4}{5}$ –2 $\frac{1}{2}$ in.) in length, with a small club-shaped head and nearly a thousand segments. The cysticerci inhabit such insects as the *asopia familiaris* (caterpillar and cocoon); the *anisolabis annuli* (belonging to the orthoptera); and the coleoptera *axis spinosa* and *scaurus striatus*. Man has been infested a

number of times, probably by taking food containing these infested insects.

Tænia Madagascariensis and *Tænia serrata* are other forms rarely found in man.

NEMATODES.

HELMINTHOLOGISTS include in this class the cylindric worms, certain varieties of which are among the most common entozoa that infest the human body and inhabit the intestines.

ASCARIASIS.

Ascaris Lumbricoides (*Round-worm*).—**Natural History.**—This species resembles the common earth-worm, and is the most frequent in occurrence of all the parasites. It usually appears in children between the ages of three and ten years. The round-worm inhabits the upper portion of the small intestine, and occurs singly or in numbers. Its body is round, fusiform, and marked with fine transverse striæ. It has a yellowish or reddish-brown color, and measures in the female from 7 to 14 inches in length (17.5–35 cm.), and from 4 to 8 inches in the male (about 20 cm.), its thickness being about that of an ordinary goose-quill. The cephalic extremity of the worm has three oval papillæ, furnished with fine teeth; the caudal extremity is straight in the female and curved in the male.

Lumbricoid worms develop from ova, which are about .05 to .06 mm. long, elliptic, dark-reddish in color, and have a thick, resisting envelope; they occur in the feces. The eggs obtain entrance into the human intestine most probably through drinking-water and food.

The round-worm sometimes, though rarely, migrates from the small intestine. It has been vomited, and it has also crawled into the pharynx, mouth, and nares, and has been withdrawn thence by the patient's fingers. It has even passed into the larynx and trachea, causing fatal asphyxia or pulmonary gangrene. The Eustachian tube and biliary ducts may be invaded with such serious symptoms as perforation of the membrum tympani and hepatic abscess.

Symptoms may be absent, and yet the worms be found repeatedly in the stools. Existing symptoms are indefinite, and point simply to an irritative condition of the bowels. Some writers ascribe them to toxins elaborated by the worms. Serious symptoms may, however, result from the migration of the worm, as into the biliary passages, Eustachian tube, or larynx. Fever is not a necessary concomitant. Lumbricoid worms may give rise to any or all of the following symptoms: colicky pains, nausea, vomiting, indigestion, diarrhea (sometimes), restlessness, irritability, anorexia, itching of and picking at the nose, disturbed sleep with grinding of the teeth, salivation, and nervous twitchings. Very nervous children may manifest epileptiform convulsions, choreic movements, dilated pupils, vertigo, cephalalgia, mental disturbances, and even contractures.

Complications.—The development of jaundice will indicate obstruction of the bile-duct, in cases in which the worms have been found in the feces. Intestinal obstruction from coiled worms has occurred. So also, suffocative symptoms coming on, especially at night, in a child with worms, may be due to a migrating lumbricoid. Perineal abscesses

and inflamed herniæ that have perforated externally sometimes discharge the *ascaris lumbricoides*.

Diagnosis.—This is positively determined only by discovering the worms or ova in the stools.

The prognosis is good, unless serious complications arise (*vide supra*), when it should be guarded accordingly.

Treatment.—*Prophylaxis.*—The water used for drinking purposes should be obtained from the purest sources.

Before giving an anthelmintic, it should be borne in mind that no good result can be certainly obtained unless the gastro-intestinal tract be nearly deprived of food for from twelve to thirty-six hours, so that the toxic action of the drug used may be exerted directly upon the unprotected worm.

Santonin is at once the most efficient and the most easily administered remedy. It may be given in doses of gr. $\frac{1}{4}$ to 1 (0.0162–0.0648) of the crystals to a child, or from gr. ij to iv (0.1296–0.2592) to an adult, in the form of a troche, before breakfast. A little milk or other light nourishment may be allowed, the troches being continued once or twice daily for two or three days. This treatment is to be followed by a brisk purge, preferably gr. j to iij (0.0648–0.1944) of calomel. I have sometimes combined small doses of calomel with the santonin in a troche, and with good effect. Xanthopsia or yellow vision, spasms, and even convulsions, and saffron-colored urine may follow the use of santonin in cases of idiosyncrasy or overdose of the drug. Oil of wormseed (*chenopodium*) in doses of five to ten drops, in emulsion, capsules, or on sugar, may also be used with benefit. Another favorite remedy with some is the unofficial fluid extract of *spigelia* and *senna*, to be given in from 1- to 3-dram (4.0–12.0) doses. Finally, the fluid extract of *spigelia* alone (1 to 2 drams—4.0–8.0), followed by a brisk purge, may bring away dead worms.

Oxyuris Vermicularis (*Seat-, Pin-, Thread-, or Maw-worm*).—

Natural History.—The *ascaris vermicularis*, as this worm is also called, inhabits the colon and especially the rectum. It is a small worm, as several of the commonly-used terms signify, and frequently it occurs in great numbers, sometimes agglutinated with mucus into feculent balls. It is most common in children, though found not rarely at any period of life. The female oxyuris is whitish in color and about ten or twelve millimeters (one-half inch) long, the male being about three or four millimeters (about one-sixth of an inch) in length. Oxyures develop from ova in about two weeks after the ingestion of the latter. The eggs are irregularly ovoid, about $\frac{1}{500}$ in. (0.05 mm.) in length, and tenacious of life. By the time the embryos have reached the cecum, they are sexually mature, and when the female arrives in the rectum, immense numbers of eggs are deposited that mature into great numbers of worms, the latter being discharged with the feces. Sometimes the worms crawl out of the anus.

Infection with the ova may take place through water and food (green, uncooked vegetables and fruit) that have come in contact with the hands of infected persons. Scratching the anus will permit of the reception of oxyuris eggs under the finger-nails (Zenker and Heller), and in careless, ignorant, and uncleanly persons the possibility of such an auto- or re-infection should be recognized and avoided.

Symptoms.—*Pruritus ani* (itching of the anus), sometimes burning pain, and tenesmus, with restlessness and disturbed sleep, are the commonest symptoms of the presence of this parasite. The itching is always worse at night, and may be paroxysmal. An herpetic or eczematous eruption around the anus should arouse suspicion, particularly in children, of the presence of the oxyuris in the rectum, and it accounts for the intense itching. Anorexia and anemia, rectal irritability, and "nervousness" may be associated. It is believed that the migration of the worms into the vagina may excite vulvo-vaginitis, pruritis, and leukorrhea, and that habits of masturbation may be induced in both girls and boys by the sexual irritation caused by the worm. Inspection of the stools will reveal, in positive cases, the whitish, thread-like parasites.

Diagnosis.—The pruritus, indicating rectal trouble, will direct the physician's attention to the anus, where the oxyures may be seen; if not found, their discovery in the feces or the discovery of the eggs by microscopic examination will suffice.

The prognosis is good, and proper treatment is always effective, though occasionally exceedingly refractory cases are encountered.

Treatment.—The exhibition of anthelmintics and purgatives, such as recommended for destroying and removing the lumbricoid worm, may be effective against seat-worms also, in reaching those lodged in the bowel above the rectum. C. W. Stiles¹ states that the adult worm lives in the small intestine and should be driven into the large intestine by an anthelmintic before local injections are given. Ashford recommends betanaphthol in 2-dram doses. Attacking the oxyures directly, however, by means of enemata is rational treatment.

The rectum should be well emptied of feces, so that the worms may be exposed to the action of the medicament injected, and for this purpose enemata of cold water, either simple or with salt or soap, may be resorted to. Injections containing the decoction of quassia (1 or 2 ounces—32.0 to 64.0—of the powder or chips to the pint— $\frac{1}{2}$ liter—of water) are nearly always curative. Other useful remedies are carbolic acid, turpentine, tannin, vinegar, camphor, potassium sulphid, and the oil of eucalyptus. The injections should be repeated once or twice daily for at least ten days.

Rectal irritation may be allayed by injections of laudanum and starch-water (gtt. iij-v to the ounce—32.0). Anal itching is often amenable to carbolized vaselin, applied at bed-time, or to belladonna ointment, or the following, which has been highly recommended:

Sig.—Apply at bedtime.

Ascaris Alata.—This is another name for the *ascaris mystax*, a species of worm found in the intestines of the dog and cat, and occasionally in man. It is a slender worm, with a closely-rolled spiral tail and a wing-like projection on either side of the head. The female is about 6-7 centimeters (2.7 inches), the male about 4 centimeters (1.75 in.) in length. Scarcely ten instances, however, have been recorded in which this parasite has occurred in man.

Trichocephalus Dispar (*Ascaris trichiura*).—**Natural History.**—

¹ "Proceedings of the Amer. Soc. of Tropical Medicine," *N. Y. Med. Jour.*, Apr. 18, 1908.

This so-called whip worm measures about four or five centimeters (2 inches) in length, and is characterized by the very slender, hair-like appearance of the anterior two-thirds of its body, in contrast to the thick posterior portion, which is more or less straight and blunt-pointed in the female, but rolled into a spiral in the male. Its particular habitat seems to be the cecum, though sometimes it is also found in the colon. It may exist in great numbers. Europeans appear to be infected with the parasite more commonly than Americans.

Propagation is effected by the microscopic eggs, which are ovoid, hard, nodular, brownish, and about 0.05 mm. ($\frac{1}{500}$ in.) in length.

Symptoms.—It is not certain that the parasite causes any symptoms.

The **diagnosis** is made by detecting the microscopic ova in the feces.

The **prognosis** and **treatment** are not called for.

UNCINARIASIS.

(*Ankylostomiasis*.)

Ankylostomum Duodenale (*Dochmius Duodenalis*).—**Natural History.**—This parasite belongs to the family of *strongylidæ* of the nematoid worms. It was discovered in Milan, in 1838, by Dubini. The length of the female is from 8 to 18 mm. ($\frac{1}{2}$ inch), and of the male from 6 to 10 mm. ($\frac{1}{3}$ inch). Its body is thread-like, with a conical-shaped head, and a large, bell-shaped mouth surrounded by a horny capsule, and possessing four hook-like teeth, ventrally situated, and two smaller, vertical teeth on the dorsal side, by which the worm fixes itself to the mucous membrane. A bulbous-like swelling exists at the tail end of the male worm. It inhabits the jejunum and duodenum. The eggs are found in muddy water, or in warm moist earth, and there liberate the embryos. These develop into larvæ, which soon enter the dormant state, remaining quiescent for an indefinite period until they are taken into the human stomach through drinking-water, food, dirt ("dirt-eaters"), or, more commonly, dirt that has collected upon the hands and about the nails. Probably direct infection through the skin, as first shown by Loos, is the usual mode of infection, however, and Allen J. Smith and others have regarded the subtropical dermatitis known as "ground itch" as an expression of this mode of infection. Loos has shown that on the completion of the exogenous phase of the embryo, the parasite enters through the skin, generally of the feet and legs, by contact with soil contaminated with the ova of the ankylostoma. Carried by the blood stream to the lungs it passes into the air vesicles, then into a bronchus, to the trachea, esophagus, and stomach, and finally to the small intestine. Here sexual characters develop in the parasites, reproduction ensues, and the ova are deposited in the bowel. They do not multiply within the intestine.

Predisposing Causes.—(a) *Geographical Distribution.*—The parasite is found in Italy, Egypt, India, Philippines, Germany, Belgium, Switzerland, and in England was found by Haldane in miners in Cornwall. B. K. Ashford¹ (U. S. Army) has shown that a large percentage of all cases of anemia occurring in Porto Rico are induced by this parasite. H. F. Harris has found the ankylostoma prevalent along the Gulf of Mexico and in the southeastern section of the United States. The importation of infected Italian, Hungarian, and Polish laborers may be accountable for the propagation of the parasite in the United States.

¹ *New York Medical Jour.*, April 14, 1900.

Stiles has studied the parasite of American origin correlatively with that known to foreign observers, and suggests the term *Necator Americanus*. (b) *Sex*.—Males and females are infected to the same extent. (c) *Age*.—The greatest infection occurs between the age of six and sixteen years (Wells).

Pathology.—The ankylostomum is probably nourished by the plasma of the blood it sucks from the intestinal vessels, though this is denied by Loos. It is found *postmortem*, sometimes, in the mucous or even sub-mucous coat, rolled up in a little blood-cavity. Ecchymoses, containing a central opening through which blood can ooze, are the usual result of the worm's action. Chronic catarrhal enteritis is usually associated. Hypertrophic dilatation of the heart is observed.

Symptoms.—The chief symptom of the condition is progressive anemia (secondary), and the skin is a pasty yellow or dirty gray color, called in the southern part of the United States "Florida complexion." When the number of ankylostoma embryos introduced into the intestine is large, the anemia may develop acutely; when but a few are introduced, the withdrawal of blood is more gradual, and *chronic anemia* develops. I think, however, it may be safely affirmed that the anemia is not wholly due to blood-sucking, but that some poisonous substance is given off by the worm, of the nature of a hemolytic toxin. The impoverishment of the blood has been so profound as to simulate a pernicious anemia.

Ashford found the red cells to vary between 700,000 and 3,525,000 per c.mm., and the hemoglobin between 10 and 55 per cent. *Leukocytosis* is not a feature of uncomplicated cases; the polymorphonuclear cells may show slight reduction, and the lymphocytes a moderate increase. Eosinophilia is common in this as in many parasitic diseases, and may reach 40 per cent. or more. In mild cases, however, eosinophilia may not be available for diagnosis, in which case the feces should be examined for eggs. The red cells are pale, of irregular size and outline; normoblasts are plentiful, and less often megaloblasts are found.

This parasite is the cause of "Egyptian chlorosis," first described by Griesinger. Ankylostomiasis is not uncommon in tropical countries. In Italy it has been termed *tunnel* or *mountain anemia*; in Belgium it is known as *brickmaker's anemia*; again, it occurs among workers in coal mines—*miner's cachexia*.

There may be, in addition, slight gastro-intestinal disorder (anorexia, colicky pains, nausea and vomiting, and constipation alternating with diarrhea). In cases marked by an acute development of anemia considerable general weakness, dyspnea, and dropsy may ensue. There is no loss in weight; but swelling of the feet and ankles, sleeplessness, headache, faintness, palpitation, and scanty perspiration are common symptoms. The renal function is maintained and slight fever may develop. Corneal ulcer is not uncommon. Lemann¹ describes infantilism in uncinariasis.

Physical Signs.—The areas of the apical cardiac impulse and of cardiac dulness are increased. Various murmurs—hemic—may be heard, and palpitation and dyspnea are common. In those affected the face is peculiarly dull, expressionless, and, owing to the marked metabolic disturbance, the growth of young subjects is greatly hindered.

Diagnosis.—This is made by finding the eggs or mature worms in the feces. The former are oval-shaped, about 0.05 mm. ($\frac{1}{200}$ in.) in length, and have a much thinner shell than the ova of the round worm. Ova

¹ *Archives of Internal Medicine*, Chicago, August, 1910.

are seen with a $\frac{1}{6}$ objective and are commonly entangled in the mucus that escapes with the feces. Suspicious specimens, if negative, should be centrifuged, Bass' ¹ method being preferable for the purpose. "If in doubt as to the diagnosis of the eggs, they may be hatched out in twenty-four to forty-eight hours and the characteristic larvæ looked for" (Dock and Bass). In cases of pronounced anemia, in which the cause is obscure, the patient's dejections should be carefully examined.

Duration.—The disease may last for months or for several years.

Prognosis.—If left untreated, the affection may end fatally. Intense anemia, obstinate diarrhea, and profound nutritive disturbances constitute symptoms of grave import. Properly treated, the prognosis is favorable, although the subject remains a carrier.

Treatment.—*Prophylactic.*—Workmen in mines, tunnels, and brick-yards, and in tropical localities especially, should be warned not to drink the water close at hand without previous boiling and then cooling. Stools infected with ankylostoma ova should be carefully disposed of and efforts at prevention of further pollution of the soil be made. The feet, legs, and hands should be protected against contamination with infected soil.

Medicinal.—Anthelmintics to kill the ankylostoma and purgatives to remove it from the intestine are indicated. The Permanent Commission for the Suppression of Uncinariasis in Porto Rico employ repeated doses of thymol and betanaphthol, preceded and followed by a saline. Brauch ² administers 30 gr. (2.0 gm.) of thymol in powder at 4, 6, 8, and 10 A. M., on an empty stomach, followed by an ounce of castor oil at 6 P. M. The State Board of Health of Florida recommends the following dosage: Under 5 years of age, up to 8 grains; 5 to 10 years of age, 8 to 15 grains; 10 to 15 years of age, 15 to 30 grains; 15 to 20 years of age, 30 to 45 grains; 20 to 60 years of age, 45 to 60 grains; over 60 years of age, 45 grains. The condition of the heart, the degree of debility and anemia should also be considered. Manson sounds a note of warning concerning the use of thymol. He says alcohol should never be given at the same time nor for some hours after a dose of thymol, as the drug is soluble in alcohol and may then exercise its toxic action on the host as well as on the parasite.

After this routine, nourishing food, fresh air, iron, and tonics are to be given.

TRICHINIASIS.

(*Trichinosis.*)

The parasite that gives rise to this affection is *trichina spiralis*.

Natural History.—The mature male worm is 0.8 to 1.5 mm. ($\frac{1}{20}$ in.) long and the female 2 to 4 mm. ($\frac{1}{12}$ — $\frac{1}{6}$ in.). The head is pointed and unarmed, and the neck is long and more slender than the body, which has a round blunt end. The worm is viviparous. It inhabits the intestines of such animals as the rat, dog, cat, hog, and man.

The embryo or muscle trichina is about 0.6 to 1 mm. ($\frac{1}{25}$ in.) long, and lies coiled up in a spiral form within an ovoid capsule in the sarcolemma-sheath of muscle-fiber. The life-history begins with the larval state of the trichinæ encysted in the muscles. When this flesh is eaten by another animal, or by man, the larvæ are liberated during the digestive process. Passing into the intestines, they reach the adult stage in from two to four

¹ "Hookworm Disease," Dock and Bass, pp. 175, 176. ² *Brit. Med. Jour.*, March 5, 1904.

days, being then sexually mature, and in five to seven days more they produce hundreds of living embryos.

The intestinal trichinæ become fully grown, and then usually die in from four to five weeks. The female trichina may bring forth several broods of embryos during her life-period in the intestine. The living embryos leave the intestine at once, and invade the muscles through various channels—principally along the connective-tissue routes—so that the symptoms of muscular irritation develop in from seven to ten days after eating the trichinous meat. The embryos attain to maturity (larval form) in about two weeks after entering the muscular tissues. Their presence causes a mechanical irritation that results in the formation of a fibrous capsule in from four to six weeks. In man it probably becomes

FIG. 27.—*Trichina spiralis* from the head of the right gastrocnemius muscle three weeks after the first symptoms appeared (Queen obj. $\frac{1}{2}$; eye piece No. II).

encysted at a later period than in the lower animals, as shown by the accompanying illustration, taken from a case under the immediate observation of Dr. L. Napoleon Boston (Fig. 27). Usually but a single worm is found within one capsule, though occasionally three or four are seen. The encapsulated trichinæ may live many years in the muscles. With increasing age the capsules become thicker and may be the seat finally of calcareous infiltration. In the hog, calcareous infiltration of the capsule is the exception, hence

the difficulty, even impossibility of seeing them with the unaided eye.

Pathology.—The diaphragm is most thickly infested with the larval trichinæ. Next in order are such trunk-muscles as the intercostals and abdominals, then the muscles of the neck, including the larynx, head, eyes, and extremities. Up to the seventh week of the disease the intestinal trichinæ may be very numerous. *Microscopically*, the muscles show “the changes characteristic of acute myositis” (Fitz) after the fifth week. The trichinous cysts in the muscles may be seen with the naked eye as small, grayish-white, opaque, “oat-shaped” specks, longitudinally disposed in the meat-fibers.

Sources of the Trichina.—The trichina was first found in pork—the usual source of trichiniasis in man—by the late Joseph Leidy. Recent investigations show that the live trichinæ may be found in the fatty as well as the fleshy portion of pork. The pig is infested by eating trichinous rats, trichinous pork, or human or porcine excrement containing the embryos of propagating intestinal trichinæ. The rat may be the original host of the parasites, or it may itself become infected by older rodents eating their fellows, or by eating trichinous pork or human or porcine excrement.

As to the frequency of the infection of hogs, it may be said that about 2 per cent. were found to be trichinous, according to Salmon's report (1884), of nearly 300,000 examinations of American pork. In Prussia, according to Eulenberg's statistics, the ratio is decidedly less varying—from 1 to 2160 hogs (1876) to 1 to 1817 (1889). “The dissecting-room

and *postmortem* statistics show that from $\frac{1}{2}$ to 2 per cent. of all bodies contain trichinæ" (Osler).

Of course, man, as a rule, becomes infected by eating raw or partially cooked pork containing living muscle-trichinæ (larvæ). Eating raw ham and sausages, a habit common among the Germans of Prussia (particularly during picnics), and in some parts of the United States where German emigrants have settled in large numbers, explains the comparative frequency of this disease in such localities. About 900 cases have been reported in the United States in the past forty-five years (Beecher). Trichiniasis has occurred in epidemic form in North Germany, France, Spain, Russia, the Scandinavian countries, and in several of the north-western United States.

Symptoms.—*Postmortem* examination often reveals the presence of unsuspected muscle-trichinæ.

In well-marked cases of infection *gastro-intestinal disturbances* appear on the second or third day after the ingestion of the affected meat. Vomiting, diarrhea, and colicky pains in the abdomen may be present. The diarrhea sometimes takes on the characteristics of a choleraic attack or may be followed by obstinate constipation.

Extreme "muscular weariness" and bodily fatigue often occur for several days before the embryonic parasites can have begun to wander into the muscles. On about the tenth to the fifteenth day, when migration usually commences, *chills*, followed by a temperature of 101.5° to 104° (38.6° to 40° C.) and marked *myositis*, come on. The muscles are stiff, tense, painful on pressure and motion, and somewhat swollen. The flexors of the extremities are particularly sore and often firmly contracted, causing the knees and elbows to be acutely bent. *Mastication*, *deglutition*, and *phonation* may be difficult and painful because of the involvement of the muscles of the jaws, pharynx, larynx, and tongue. Intense *dyspnea* is frequent on account of the involvement of the diaphragm and intestinal muscles. The *temperature* shows marked remissions in most cases, and may even be subnormal. The *pulse* varies with the temperature.

Edema is characteristic in nearly all of the cases. It appears on about the seventh day after the infection, and begins in the face (frontal region), usually being noted first in the eyelids, and extending thence to the extremities and trunk during the height of the muscular symptoms. It may last for several days, then disappear for several days or a week, and reappear. Ascites even has been observed. Edema of the larynx and bronchial catarrh, the latter rarely leading to broncho-pneumonia, may also supervene and add to the gravity of the dyspnea. Profuse sweating may last for several weeks. Miliaria, urticaria, acne, furunculosis, herpes, and pruritus may occur as skin-manifestations. Insomnia, headache, a temporary loss of the tendon-reflexes, and dilatation of the pupils (Rupprecht) have been noted among the nervous symptoms. Prolonged cases show a marked degree of emaciation and anemia. T. R. Brown¹ found a decided increase of the eosinophiles in the blood, amounting to 37 per cent. This discovery has been confirmed. W. T. Howard, Jr.,² noted eosinophiles in the muscle-lesions, but failed to find an increase of these cells in the circulating blood. Opie³ administered trichina spiralis to the guinea-pig, and found that a resulting mild infection

¹ Johns Hopkins Hospital Bulletin, 1897, vol. viii.

² Phila. Med. Jour., December 2, 1899.

³ Amer. Jour. Med. Sci., March, 1904.

stimulates the eosinophile cells to active multiplication, but severe infection causes their destruction. A marked, absolute leukocytosis is the rule.

There is little doubt that the "muscle symptoms," varying with the site of the muscle attacked, can be explained on the basis of a reactionary inflammation, a true myositis existing about the parasitic cysts as Brown has shown, but the general symptoms are probably—in part at least—due to some toxic emanation from the parasite itself.

Complications, as a typhoid state, hypostatic pneumonia, and pleurisy may appear. Albumin, with casts, are found in the urine.

Recovery is effected in mild cases within two weeks, while in the severe ones from six weeks to several months may be occupied.

Diagnosis.—The following symptoms are regarded as pathognomonic: sudden swelling of the face, coming on after the patient has suffered for several days from muscular soreness; loss of appetite, fever, and profuse sweats (Böhler); painful, tender, and "rubber-like" hardness of the muscles, with difficulty in movement; semiflexed extremities; gastro-intestinal catarrh, with a red, dry, coated tongue; dyspnea, diarrhea, and edema of the extremities following the subsidence of that first noticed in the face. Friedreich emphasizes hoarseness, and the late Dr. Packard rapidity of respiration without evident cause.

Differential Diagnosis.—*Meat- and sausage-poisoning* may be distinguished from trichiniasis by the more rapid course of the former, the dry throat and skin, jaundice, visual disturbances, and the absence of edema and muscular symptoms.

Direct examination of the passages and of the muscles may be resorted to. The discovery of the parasites in the pork a portion of which has been eaten by the sick establishes the diagnosis. A low-power microscope should be used to examine the intestinal mucus for the trichinæ. Light purgation should precede this endeavor. Harpooning such muscles as the biceps for the purpose of removing some muscle-fiber, or directly incising a small portion under Schleich's method of infiltration-anesthesia, may permit of a positive diagnosis.

Acute rheumatism, cholera, typhoid fever, and acute polymyositis (pseudo-trichiniasis) may at times resemble trichiniasis. Epidemics of the parasitic disease are more readily diagnosed than an isolated case.

Prognosis.—This depends upon the number of parasites ingested and upon the number of embryos generated in the intestines. Marked early diarrhea is favorable. The prognosis should be guarded, as death may occur as late as from the fourth to the sixth week. Of 357 cases collected by Packard, the mortality was 24.07 per cent.

Treatment.—Prophylaxis is of supreme importance, both as to the infection of the hog and the danger of eating infected pork. Care should be exercised in the feeding of swine, and the destruction of rats should be made as complete as possible in and about the styes. Pig-excrement should be removed and burned, and feeding with milk, bran, grain, and vegetables should be forced upon all keepers of swine.

Rigid inspection of the meat-supply, as is done in Germany, should be carried out by government sanitary officers. Decidedly the safest and most efficient way to prevent trichinosis is to thoroughly salt, smoke, and cook the pork that is to be used. Putrefaction does not kill the parasites.

The treatment of those who have eaten trichinous meat should be by a prompt evacuation of the bowel, especially within the first twenty-four

hours, as after the embryo young have been brought forth and have passed into the muscles no known treatment is successful in attacking them. Calomel is one of the best drugs, and active purgation usually follows its use in large doses, succeeded by salines; rhubarb, senna, sulphur, aloin, and large doses of oil or glycerin may also be tried. In combination with the purgatives some anthelmintic (male fern, santonin, thymol) should be used. The encysted or larval parasites are not accessible to treatment, although picric acid has been recommended. The symptoms to be met are the great muscular pains, insomnia, and weakness, which is often severe in protracted cases. Prolonged hot baths,

FIG. 28.—The movement of a single filaria during a series of four successive instantaneous exposures. The length of each exposure was one-fifth of a second, the entire series occupying less than five seconds. The magnification is to eight hundred diameters, with a Zeiss one-twelfth homogeneous immersion lens (F. P. Henry).

FIG. 29.—Filaria alive in the blood. Instantaneous photomicrograph. Four hundred diameters magnification. Four millimeters Zeiss apochromatic (F. P. Henry).

anodyne embrocations, with hypodermics occasionally, may prove useful for the first; bromids, chloralamid, and the like for the second symptom; and a concentrated liquid diet, strychnin, peptonoids, and the like for the last. Massage, electricity, and stimulating applications, as chloroform liniment, may be required during convalescence and for some time thereafter to combat the muscular weakness, soreness, and stiffness.

FILARIASIS.

(*Filaria Sanguinis Hominis*.)

There are several varieties of filariæ that may be found in human blood. The two principal ones are the *filaria sanguinis hominis nocturna* and *filaria sanguinis hominis diurna*. But two other distinct species of nematode worms infest the blood of tropical man according to Manson. These are *filaria perstans* and *filaria demarquai*. Of these various forms the *filaria nocturna* is the most important and the best known. The adult forms, male and female, found only in the lymphatics, are

called *filaria Bancrofti*; the embryos, which alone are found in the circulating blood, are termed *filaria nocturna*. The first is a white, opaline thread-like worm, tapering toward the ends, which latter, however, are blunt. The male is 83 mm. (3.2 inches), the female 155 mm. (6.1 inches) long. The second worm is known only in embryonic form, and is distinguished by granulations in the axis of the body. This is the *filaria diurna*, of which the adult form is said to be the *filaria loa*, now known to be the cause of Calabar swellings. Manson found them in the blood of Congo negroes, but only during the daytime. On the other hand, the nocturnal *filaria* is found only at night, or, if the host be either by habit, necessity, or choice, a day sleeper, during this time, showing, then, that there is some condition of the body during quietude that is conducive to the appearance of the *filaria* in the blood (Granville). Manson observed that during the diurnal temporary absence of the *filariæ* from the cutaneous circulation they are found principally in the larger arteries and the lungs. This "filarial periodicity" is a striking characteristic. Inversion cannot be induced in cases of *filaria diurna*.

Filaria philippinensis is also worthy of mention. Ashburn and Craig conclude: (a) That the complete development of *Filaria philippinensis*, discovered by them in 1906, has been followed in the mosquito, *Culex fatigans*; (b) that the *Filaria philippinensis* is distinguishable from other *filaria* "both in the blood and during the developmental cycle within the mosquito"; (c) that as regards the time of its occurrence in the blood, the organism presents no periodicity.

The embryos of *filaria sanguinis hominis* are produced by the female in great numbers, and are so small that they readily pass through the capillaries. According to Manson, who, in 1877, found the larvæ in the stomach of a female mosquito, it is probable that after filling itself with the blood of an infested man during sleep, the mosquito seeks stagnant water, dies, and the larvæ are set free. In this way it may happen that man takes in the embryos through the drinking-water. More recently it has been shown that the *filaria*, once in the stomach of the mosquito, sheds its delicate envelope, then pierces the wall of the mosquito's stomach and lodges in the thoracic muscles. Here it undergoes further developmental changes during two weeks, then finds its way into the proboscis, to be discharged into the blood of the human host. They find a permanent seat in the lymphatics of the human host, mature, and bring forth young, which may again infest the blood by passing through the lymph-ducts into the thoracic duct and general circulation.

The geographic distribution of filariasis is limited mainly to the tropics and sub-tropics. It is most common in Brazil, the West Indies, Mexico, the Southern States, Southern China, India, Egypt, a part of Australia, and the southern Pacific islands, where it is endemic.

The **symptoms** of filariasis are in abeyance until some obstruction and inflammation of the lymph-channels is caused by the parasite. There are several conditions or endemic diseases produced. **Elephantiasis arabum** is believed by Manson to be the effect of these parasites, in a certain proportion of cases at least. In specimens of night-blood from 88 Cochinchinese he found *filariæ* in 21; 14 specimens came from patients with elephantiasis, and only 1 showed *filariæ*. This latter fact, he explains, is to be expected, since, in order to give rise to elephantiasis (due to an infarction of the lymphatic glands connected with the diseased areas), the adult *filariæ*

must lie on the distal side of the glands, which makes it impossible for the young filariæ to pass into the general circulation. "Therefore the person least likely, in a filarial district, to have filariæ in his blood is one who is the subject of elephantiasis."¹

Hematochyluria and Chyluria.—The patient passes a white, opaque, milky urine, occasionally bloody, with a clotty sediment. This may be intermittent, and normal urine may be passed for many weeks before chyluria or hematochyluria reappears. There may be at the same time a slight degree of polyuria. Under the microscope, fat granules and white and red corpuscles are seen. The lively, wriggling embryo filariæ may also be discovered in the urine, as well as in the blood at night. There is a dilatation of the lymph-vessels in the kidneys alongside of the tubules, and in the abdominal lymph-plexuses. Sometimes a little vesical irritation and straining during urination may be caused by the endeavor to pass chylous blood-clots. The thoracic duct above the diaphragm has been found impervious (Stephen Mackenzie).

Lymph-scrotum and lymph-vulva have been caused by the filariæ. The parts are greatly swollen, thickened, and contain distended lymphatics filled with a turbid and either milk-white, salmon-colored, or blood-red coagulable liquid that is discharged upon puncturing the varices. The filaria is not always found in the exuded lymph. The inguinal and femoral regions are often enlarged. An erysipematous inflammation of the parts is not infrequent in these cases, and may be ushered in by a chill and high fever, lasting a day or two, and ending with a profuse sweat.

The filariæ have been found in ascites (Winckel), in hemoptysis, and in the feces (Yamane, Japan). Worms killed by blows or other injuries are often absorbed, but may act as an irritant and cause abscesses.

Treatment.—Healthy subjects must protect themselves against mosquito bites. Filtering, boiling, and storing the drinking water in mosquito-proof receptacles are important measures. Thymol, in from 1- to 5-grain (0.0648–0.324) doses, given for from two to eight weeks, has caused the disappearance of the larval filariæ in several cases. Methylen-blue appears also to have produced a cure in a case of chyluria reported by Flint. Henry, however, states that he has "given this drug in larger doses than were used in the case reported by Flint, and for a much longer period, without the slightest effect upon the parasite."² The adult filaria seems to be beyond the reach of any known medication that will not prove dangerous.

DRACONTIASIS.

(Guinea-worm Disease.)

The parasite is the *filaria* or *dracunculus medinensis* or *persarum*, common in the tropics of Asia, Africa, and America. It is usually solitary, and measures from 50 to 100 cm. (20 to 40 in.) in length and about 2 mm. ($\frac{1}{12}$ in.) in diameter. It is cylindric, whitish, with blunt papillated head, and a sharp, curved tail. The body is nearly filled by the uterus, which contains innumerable embryos, which, after maturation of the worm, escape shortly after contact with water in the form of a milky fluid. The process of emptying the uterus takes from two to three weeks. This accomplished, the worm dies. It is then taken into the stomach and in-

¹ *British Med. Jour.*, June 2, 1894.

² *Med. News*, May 2, 1896.

testines of man through the contaminated drinking-water. The female enters the intestines by way of the mesentery and brings forth its young, which pass into the connective tissue of its human host. The male worm is unknown. The worm has an inexplicable affinity for the subcutaneous and intermuscular tissues of the feet and legs, where it attains full development.

Symptoms.—Wherever the parasite is situated, it may often be felt coiled up under the skin, which at that point becomes red and fluctuating like an abscess. When opened, either surgically or naturally by the worm, the head appears through the aperture. The favorite spot for perforation is the dorsum of the foot, though sometimes it extrudes from the legs, rarely the thighs, and very rarely from the thorax and abdomen.

Treatment.—Prophylaxis in regard to the drinking-water and as to bathing where the intermediary host of the dracunculus—the cyclops—has its habitat is essential for safety.

The treatment embraces the surgical measures necessary to remove the worm and to promote the healing of the irritated tissues. Roth claims that after incision the application of carbolic acid (1 : 15) causes the worm to be removed in two or three days. Native Indian physicians commend highly the local application of the leaves of the “amarpattee” plant.

OTHER FILARIÆ.

Among other filariæ that have been found in man are the following: The *filaria immitis*, which causes hematuria and has been found in the portal vein, whilst the ova were discovered in the ureteral and vesical walls; *filaria labialis*, found in a lip pustule; *filaria lentis*, found in a cataract; *filaria trachealis* and *bronchialis*, seen in the trachea, bronchioles, and lungs; *filaria hominis oris*, observed by Leidy in the mouth of a child; *filaria loa*, noticed in the tropics among negroes, its habitat being beneath the conjunctiva. Recently L. N. Boston found *filaria mermus* (according to Wardell Stiles, to whom he referred them) in a cavity in the centre of an apple. They are believed to be parasites of the apple worm, but whether pathogenic, is not known.

OTHER AND UNCOMMON NEMATODES.

Eustrongylus Gigas.—This parasite is exceedingly rare in man, but has been found in many of the carnivora and in some herbivora. It is supposed that fish act as the intermediary host for the larvæ. The worm is enormous in size, the female being from 25 to 100 cm. (10 to 40 in.) in length. It is a red, cylindric parasite with blunt-pointed ends. Its seat is the kidney, which it may destroy, causing hematuria and the presence of the eustrongylus ova. Dr. John McKenna has recovered an adult eustrongylus from a child whose urine had long contained ova.

Anguillula stercoralis or **strongyloides intestinalis** occurs in the stools of certain tropical endemic diarrheas. It is common along the Gulf of Mexico. The parasites are oviparous, and the eggs may be taken through the drinking-water. They have been found in the biliary and pancreatic ducts, as well as in various parts of the intestines. The administration of thymol or male-fern is to be recommended.

Echinorhynchus moniliformis occurs in rats, and in one case, that of a Sicilian, reported by Calandrucchio, the ova were found in the feces.

PARASITIC ARACHNIDA.

Pentastoma Tenioides.—This parasite is an inhabitant of the nasal fossæ of the dog or horse, though it may also occur in man both in this and in the larval form. The ova are ejected during sneezing, and are then ingested by man. The larvæ are found in the liver, lungs, and kidneys.

Sarcoptes (Acarus Scabiei).—This insect produces the skin affection known as “the itch,” or *scabies*, an affection more common in Europe than in America, where it constitutes only about 4 or 5 per cent. of all cases of skin disease. It is most prevalent among the poor and the unclean. The female is visible to the naked eye, and is about 0.5 mm. ($\frac{1}{50}$ in.) in length; the male is about 0.25 mm. ($\frac{1}{100}$ in.). Both are nearly as broad as they are long.

The parasite penetrates the skin and lives in a burrow or *cuniculus* that it makes for itself. The female lives in the end of the burrow, which may contain a number of ova, and appears as a minute, brownish-black, dotted, sinuous line, situated chiefly in the cutaneous folds, where the skin is mostly delicate, as between the fingers. Secondary skin lesions, due to scratching, are common. Sulphur ointment, well rubbed in after hot bathing, is usually quite efficacious.

Sarcoptes scabiei hominis is a variety of the preceding that infests other animals (cat, dog, cow, horse, wolf, goat, camel, etc.). Occasionally it may gain an entrance into man's skin, but dies simultaneously in the human host, although many invasions may occur.

Leptus Autumnalis (Harvest Bug).—The most common of several varieties is a mite of a reddish color, having six legs armed with claws and sharp mandibles. It arises among low bushes and thus appears about the ankles and legs. It partially penetrates the skin, boring only far enough with its short, thick head to procure nourishment. Artificial dermatitis may be produced by the irritation of scratching. Mercury, sulphur, and naphthol ointments suffice to destroy the parasite.

Demodex Folliculorum (Comedo Mite).—This minute parasite may be expressed from swollen sebaceous follicles of the nose, cheek, and other parts of the face. It has a worm-like body with very short legs, and is only about 0.2 to 0.4 mm. ($\frac{1}{60}$ in.) in length. It is not known to produce acne, as was formerly supposed.

OTHER PARASITIC INSECTS.

PEDICULOSIS.

(*Phthiriasis*.)

Lice or *pediculi* live on and attack the skin. Three forms are found on man: *pediculus capitis*, *pediculus corporis*, and *pediculus pubis*.

The *pediculus capitis* is whitish or grayish in color, about 1 mm. ($\frac{1}{25}$ in.) long (male), and has six legs under the front part of the body. The oviparous female is nearly twice as long as the male, and lays from fifty to eighty eggs on the hairs within a week. These ova, or “nits,” mature in from three to eight days. Itching is the most prominent symp-

tom, and an eczematous eruption above and behind the ears and in the neck is often associated. "*Plica polonica*" was a phrase once used to designate the matted condition of the hair in extremely dirty, crusty, and long-neglected cases of head-lice. Secondary adenopathy of the cervical lymphatic glands is a common feature in neglected cases.

Pediculus Vestimentorum (*Corporis*).—This louse inhabits more often the clothing than the body itself. It is larger than the head louse, and, like the latter, moves slowly. The nits are found with difficulty on the fibers of the underclothing. It sucks blood through a proboscis inserted into the sweat pores, and after withdrawing leaves a minute hemorrhagic speck. Irritation of the skin is produced, and in old cases, as in filthy tramps, the skin becomes scaly and quite pigmented (vagabond's disease). The efforts at scratching are almost frantic, and after a cure is effected parallel white lines, the remains of scratch-marks, followed by atrophic changes, may be visible, as in a case that I reported.¹

Pediculus or Phthiriasis Pubis (*Crab-louse*).—This parasite is not limited to the pubis, but attacks also the hairy region in the axilla, on the chest, and may even reach the beard and eyebrows. It clings firmly to one or two hairs close to the skin. Its six legs with strong claws are placed closely together at the anterior part of the ovoid body.

Treatment.—The hair should be cut short where the head-lice and nits are abundant. Saturating the hair and scalp with kerosene oil for twenty-four hours usually kills the parasites. *Body-lice* may be destroyed by scalding the underclothing and hot-ironing carefully about the seams. A hot soap-and-water bath is sufficient for the body, and sedative and antiseptic ointments may be useful adjuvants. Mercurial and beta-naphthol unguents usually suffice in treating for *pediculus pubis*. Prof. J. V. Shoemaker² affirms that naphthol is a remedy that seems to meet the indications presented by the three forms of the disease; he prepares it as follows :

Ry. Beta-naphthol, 3j (4.0);
Cologne water, f3iv-vi (120.0-178.0).—M.

Cimex Lectularius or *Bed-bug*.—This too well-known parasite is flat, brownish-red in color, and from 2 to 5 mm. ($\frac{1}{12}$ – $\frac{1}{5}$ in.) in length. It infests beds and public vehicles, emitting a disagreeable odor. It is a blood-sucker, and causes considerable itching, local irritation, and urticaria even in some persons, while others are unmindful of their attacks. Sulphur fumigation and mercuric chlorid applications to the harboring places of the bed-bugs are effectual destructive agents. Saturated sodium bicarbonate solution will relieve the burning and itching.

Pulex Irritans (*Common Flea*).—This "ubiquitous" parasite is from 2 to 4 mm. ($\frac{1}{12}$ – $\frac{1}{6}$ in.) in length, black or (when filled with blood) brownish-red in color, having six legs, the hind ones of which are relatively very large and powerful, enabling it to jump many times its own height. A flea's bite causes a sharp sting, and leaves a slightly raised red spot with a dark, pin-point center, the site of penetration of the biting apparatus of the insect. Treatment is the same as for the preceding insect.

¹ *International Clinics*, vol. iii., third series, p. 769.

² *A Practical Treatise on Diseases of the Skin*, p. 849.

Pulex Penetrans ("Jigger").—This parasite, also called "sand-flea," is indigenous to the West Indies, South America, and the Southern States. The impregnated female penetrates the skin, and especially that of the feet, for purposes of ovulation. As the distention with the eggs occurs, swelling, pain, and even ulceration may appear. The sand-flea is a small, egg-shaped insect, about half the size of an ordinary flea, brownish in color, and exceedingly resistant to crushing force. *Prophylaxis* in regard to foot-wear is necessary. Essential and antiseptic oils may also be put on the feet or stockings.

Ixodes (*Wood-tick*).—There are several varieties of tick- or wood-louse that may attack the human skin, among which *ixodes albipictus* is supposed to be the most common. *Ixodes ricinus* and *ixodes bovis* are found on horses and cattle. They are blood-suckers, adhering to the skin very firmly, and wheals may be produced by them. A drop of turpentine, or of some such essential oil as anise or rosemary, will cause them to loosen their hold.

Dermanyssus Avium et Gallinæ.—These bird- and fowl-insects are small and grayish-white in color, and may attack the human skin and cause eczematous eruptions, owing to the scratching induced by the irritation.

Culicidæ (*Mosquitoes and Gnats*).—The blood-sucking mosquito (*culex auxifer*), so well known, may also transfer to human beings the filaria sanguinis hominis and the plasmodium malarie.

The gnat (*culex pipiens*) is very troublesome during certain seasons, particularly along water-courses and in wooded districts. Its bite is quick, sharp, and stinging.

The *hirudo* (leech) is a parasite that sometimes attaches itself to bathers. In the tropics it has been known to cause severe bites and inflammation. A remarkable case of hemoptysis is on record in which a leech was found attached to the larynx, below the cords.

The bites and stings of bees, wasps, spiders, and ants have been known to cause considerable inflammation, edema, and blood-poisoning.

Estridæ (*Bot-flies*).—These may become parasitic in man in the larval form. Species of the *hydroxerma* and *dermatobia*, that infest the skin of the horse, ox, goat, etc., have also been observed among the Central and South American Indians. They burrow beneath the skin of the abdomen, scrotum, and other regions.

Muscidæ (*Common Flies*).—Common flies affect the skin of man by depositing eggs in wounds. The ova hatch within twenty-four hours sometimes, and the dipterous larvæ may swarm to make the so-called "living" wound or sore (*myiasis vulnerum*). The larvæ or maggots do not penetrate the tissues, however. The principal flies that infest wounds are the flesh-fly (*sarcophila carnaria*), the blow-fly (*calliphora vomitoria*), the screw-worm fly (*compsomyia macellaria*), and the ordinary house-fly (*musca domestica*).

Internal myiasis may also be caused by swallowing the ova of these flies. The larvæ may thus be vomited or defecated.

Epidemic urticaria is often caused by the migration of the caterpillar (*cnethocampa*). Among other parasites that attack man and inhabit particular regions are the following: The *simulium reptans*, or creeping gnat of Sweden; the *seroot-fly* (*zimb*) of Abyssinia; the *ixodes carapato*, a virulent bed-bug in Brazil; the *hæmatopota pluvialis* (Clegg) of the West Highlands.

SYPHILIS.

Definition.—A chronic infectious disease communicable from person to person by direct or indirect contact with a specific virus, or by heredity. According to its clinical course, it is characterized by five periods: (1) Period of primary incubation—the time which elapses between contact with the poison and the appearance of the chancre. (2) Period of secondary incubation—the time which elapses between the appearance of the initial lesion of the disease (the chancre) and the development of its cutaneous manifestations. (3) Period of secondary symptoms (skin eruptions). (4) Intermediary period characterized by the absence of lesions, although evidences of existing dyscrasia can still be found. (5) Period of tertiary symptoms. The hereditary form of the disease is transmitted at the time of procreation by the sperm virile, by the ovum, or by both. Prince Morrow¹ points out that the important lesions of the disease are those that occur in the internal organs—*visceral syphilis*.

General Pathology.—(a) **Primary Lesion of Chancre.**—This appears at the site of inoculation, and is characterized by infiltration of the connective tissue chiefly with round cells of the same type as those seen in recent granulations. There is sclerosis of the small blood-vessels, chiefly involving the adventitia of the arterioles. The neighboring lymphatic glands soon undergo hyperplasia and induration.

(b) **Secondary Lesions.**—Macular and maculo-papular eruptions are frequent, and, with the mucous patch, show round-cell infiltration of the connective tissue and blood-vessels similar to that found in the chancre, with plasma cells and leukocytes. The favorite sites for mucous patches are the mucocutaneous junctions (mouth, anus, etc.). Other lesions of this stage are general adenopathy, alopecia, and pharyngitis.

(c) **Tertiary Lesions.**—These are circumscribed inflammatory products known as gummata. They appear in the connective tissue, bones, periosteum ("nodes"), skin, muscles, brain, liver, lungs, kidneys, heart, testes, etc. The gummata, though usually sharply circumscribed, may take the form of diffuse infiltrations and vary in size—from a pin's point to a hen's egg. Usually firm, they may be soft, and tend to form ulcers. Their color is grayish, and on section they show a caseous, semi-opaque center, with a fibrous, translucent periphery.

Microscopically, the gumma consists of lymphoid cells, plasma cells, leukocytes, and epithelioid cells, in which fatty degeneration and softening result in the formation of a pasty mass. The mass thus formed may either be absorbed or persist; but in most instances coagulation-necrosis occurs in the center, with conversion of the peripheral zone into fibrous tissue. Gummata of certain structures (skin, mucous membrane, bones, and cartilages) often lead to destructive ulceration and sloughing.

General Etiology.—**Bacteriology.**—Schaudinn and Hoffman² described two spiral micro-organisms; one, from the deeper layers of the chancre, condylomata, and lymph-glands, the specific organism, or the *treponema pallidum*; while from the superficial part of the lesions, the non-specific *spirochaeta refringens*. The *treponema pallidum* in length varies

² *Deutsch. med. Wochenschr.*, May 4, 1905.

¹ *Medical News*, March 23, 1901.

from one to six times the diameter of a red blood-cell, in width from unmeasurable thinness to $\frac{1}{2} \mu$. Metchnikoff and Roux¹ have demonstrated this organism in acquired syphilis of man and in experimental lues in the monkey and ape.

Predisposing Causes.—Since acquired syphilis originates only by inoculation, it is obvious that a break in the cutaneous or mucous surfaces is essential to infection, such as a slight abrasion, fissure, or laceration, etc., particularly of the genital mucosæ. Other surfaces may also be the seat of infection, as the lips, hands, etc.

Susceptibility to the virus is universal, and no age is exempt. *Re-infection* is exceedingly rare, but does occur.

Contagion of Syphilis.—The blood of a syphilitic during the secondary period, and the secretion from the chancre or any of the secondary lesions, are contagious, the lesion at the point of inoculation always being a chancre. The physiologic secretions, saliva, sweat, milk, and semen, do not convey the virus, unless contaminated with the discharges from some of the lesions of the primary or secondary stage. The semen is able to infect the embryo and, in turn, the mother. There is experimental evidence to show that the gumma is infectious.

Modes of Infection.—(1) In a great proportion of the cases (about 70 per cent) syphilis is transferred by illicit sexual intercourse.

(2) *Accidental Inoculation.*—This is not uncommon. (a) Most frequently it is accomplished through the pernicious custom of indiscriminate kissing (lip-chancere), and I have personal knowledge of not less than 8 instances in which infection has occurred through labial contact. In Russia from 75 to 80 per cent. are acquired in this manner from popular customs.

(b) The site of inoculation may also be the mouth and tonsils, the virus being conveyed during the low practices of sexual perverts or by kissing. The wet-nurse may infect the mouths of suckling babes, or, *vice versa*, the infant may infect the nipple of the nurse.

(c) The obstetric finger may become infected. Three instances of the sort have come under my own observation, and Fournier gives the details of 40 cases of primary syphilitic infection of the hand. In 30 of these the malady was acquired in medical practice (4 obstetricians, 20 general practitioners, 3 students, and 3 midwives). Montgomery² states that chancre of the finger is peculiarly frequent in physicians.

(d) Humanized vaccine virus may rarely transmit the disease.

(e) Accidental infection has, at times (though very rarely), taken place in a variety of other ways—*e. g.*, handling foul rags from the hospital ward, by bed-clothing, drinking-cups, the pipe and cigar, tattooing, etc.

Krafft-Ebing found that out of 3455 cases 15 $\frac{6}{10}$ per cent. were of extra-genital origin. The lesion was upon the lips in 51 per cent.

(3) *Hereditary Transmission.*—Paternal transmission (through the semen) is much more common than is maternal, the period of greatest danger being immediately after the father has become infected or during the time of the secondary manifestations. The first-born, if the father be syphilitic, is apt to show well-marked lesions. Appropriate treatment of a syphilitic parent lessens the danger of transmission very

¹ *Bulletin de l'Académie de Médecin*, Paris, May 16, 1905.

² *Jour. Cutan. Diseases*, April, 1905.

materially, however, and in such instances there is little tendency to transmission shown after the third year. On the other hand, a syphilitic father or mother may beget healthy offspring, the infant having acquired some immunity which protects it from its mother (Profeta's law). Syphilitic children are also common to infected women. In the majority of instances of hereditary transmission, however, both parents are syphilitic, and under these circumstances the liability to infect the offspring is much augmented. A woman who has become infected after conception may bear a syphilitic child; though the latter may, on the other hand, escape infection.

Allusion may here be made to Colles's law—that a woman who bears a syphilitic child enjoys, owing to a sort of protective vaccination with the specific virus, perfect immunity, and this in the absence of all signs of the affection. Couetts¹ dissents from this opinion.

Clinical History of Acquired Syphilis.—(a) Primary Stage.—

The typical *initial lesion* (chancre) appears about three weeks after infection, and is followed soon by swelling and induration of the nearest lymphatic glands. The primary sore begins as a *red papule*, which rapidly reaches its maximum, and then undergoes a central necrosis with the formation of a *small ulcer*. The adjacent structures become hard or cartilage-like—a characteristic to which the lesion owes its name of “hard chancre.” A small chancre may often escape detection, especially if it be situated inside the meatus. When situated upon a mucous membrane it is always a *chancreous erosion*, which may be so mild and of such brief existence as to come and go without the knowledge of its bearer. Particularly is this the case in the female. The *general symptoms* are negative in this stage.

(b) **Secondary Stage.**—This is announced about six weeks after the appearance of the infecting chancre by *moderate fever* (100°–101° F.—37.7°–38.3° C.), exceptionally higher, accompanied by languor, headache, bone-pains, impaired digestion, and a slight degree of prostration. There is angina, with hyperemia of the fauces and hard palate. The blood shows a marked reduction in hemoglobin with some diminution in the number of red cells. *General lymphatic enlargement* is seen, especially significant in the post-cervical and epitrochlear glands.

Skin eruptions are of many forms. The *erythematous* or *roseolar* is the earliest and most common, coming out abundantly upon the trunk (especially the chest), buttocks, thighs, and forehead. Another early variety is the *papular*. The papules are small or large, hard, and appear on the face, trunk, and flexor surfaces of the extremities.

Mucous patches may appear on the visible mucous surfaces (angles of mouth, tongue, tonsils, pharynx, vulva, vagina, penis, and around the anus), and are among the early and constant lesions. The distribution of these early syphilids is symmetric; their outlines are rounded; their color like that of a slice of raw ham (“coppery”); they are polymorphous; and, as a rule, they excite neither pain nor itching.

Other and later-appearing eruptions may be *pustular*, and *tubercular*. These show a tendency to bunch in certain areas, and hence are less diffuse than the afore-mentioned eruptions; and are not symmetrically distributed on the body.

¹ “Hunterian Lectures,” *Lancet*, 1896, No. 3889.

Other frequent symptomatic conditions arise during this secondary period, such as alopecia, laryngitis, iritis, choroiditis, retinitis, and epididymitis (more rarely). The hairs of the eyelids and eyebrows may fall off and the finger-nails become brittle.

The *secondary* symptoms last from two to three months (the usual duration) to a year or more, and are followed by a period of apparent good health lasting for an exceedingly variable interval (from a few months to many years) before the tertiary stage sets in. During the secondary stage the symptoms may be severe, mild, or even absent. There is a *late secondary* syphilis, the symptoms appearing a variable number of years after the primary lesion. Fournier states that late secondary phenomena occur most often in cases that have been well treated.

(c) **Tertiary Stage.**—As I have already stated, the secondary period is generally followed by a variable interval of freedom from symptoms, but to this rule there are numerous exceptions, and among not uncommon occurrences may be witnessed the appearance of tertiary symptoms during the secondary stage. As stated by R. W. Taylor, "By far the most potent and frequent cause of tertiary syphilis is the absence or insufficiency of treatment during the secondary stage." Belonging to the third stage are certain skin-eruptions, especially the characteristic *rupia*, which first appears in the form of pustules that break and form ulcers that are covered with dry, laminated crusts "like an oyster-shell." To this stage also belongs the *tubercular* variety, affecting the face, back, and legs, and very commonly the elbows, and rarely other portions of the bodily surface. These eruptions involve the true skin, and in healing leave scars, but, unlike the secondary cutaneous lesions, they are neither infectious nor contagious, are not, as a rule, symmetric, and are more liable to be attended by itching. A purpuric syphilid (blood-extravasation form) is also met with in this stage. True *gummata* may develop in the skin and subcutaneous tissue, and these break down and form kidney-shaped ulcers which tend to spread in a serpiginous manner. On healing (a process that is accomplished with difficulty), scars result. Gummata may occur in the mucous membrane and pass through the stages of ulceration and cicatrization. When situated in the larynx or trachea, their healing is attended with narrowing of the organ, and when in the lower bowel or the rectum, dysenteric symptoms, followed by actual stenosis, may result.

In the muscles gummata occur and form small hard tumors. They may also cause periostitis and death of the bones, especially of the nose, palate, and skull; "nodes" are thus formed, which are situated chiefly upon the tibia and the skull in larger or smaller numbers, and also, though less frequently, upon other bones. These are exceedingly painful, particularly at night, and are very tender under the pressing finger. They may be true gummata, but more often, if not absorbed, they either become ossified or undergo fibroid change, while in rarer cases they suppurate. Chronic enlargement of the lymphatics and of the testicle, with little tendency to suppuration, may be noticed. The pregnant female is apt to abort or miscarry.

Gummata also occur in the internal organs (*visceral syphilis*), and of the latter I shall speak presently, taking up separately some of the various organs and systems of the body. *Amyloid degeneration* is frequently caused by the acquired form, particularly syphilis of the rectum in women, but very rarely by the congenital.

Malignant Syphilis.—By this term is meant a virulent and a fatal form of the malady which is fortunately rare. The various stages manifest themselves early, and especially the tertiary, as on the forty-fifth day in a case of Mauriac. The course is rapid and the condition resists all forms of treatment. Roussel narrates a case in which death occurred about one year after the commencement of the disease.

Clinical Symptoms of Hereditary Syphilis.—These may, though rarely, be identical with those of acquired syphilis, if we except the chancre.¹ Occasionally the characteristic symptoms are present at birth. On the other hand, in the vast majority of instances, they appear between the first and fourth months of life (*infra*). The symptoms of *inherited syphilis* may be grouped according to the time of appearance. Kassowitz² states that one-third of all children procreated of syphilitic parents are born dead, and of those born living 24 per cent. die within the first six months of life.

(1) **In the New-born.**—There is a lack of physical development. The babe may be *greatly emaciated*, it has snuffles, and singultus occasionally sets in soon after birth. Skin-eruptions are rare, except *pemphigus neonatorum*, which appears as bullæ on the palms and soles; among exceptional cutaneous phenomena are gummata around the radio-carpal articulations, palmar psoriasis, and a fleeting roseola. Ulcers and fissures (*rhagades*) may be noticed around the outlets of the body (mouth, anus, etc.); the osseous system may show hyperostoses of the long bones; and the liver and spleen are enlarged. Comby reports 8 cases of pseudo-paralysis due to syphilis in the new-born.

(2) **Early Post-natal Symptoms.**—Most subjects of syphilis hereditaria are born *plump* and *without taint*. Symptoms appear in the majority of cases not later than the third month.

The first symptom is generally *coryza* (syphilitic rhinitis), which is betrayed by a sero-purulent or bloody discharge and a peculiar form of *obstructed breathing* (snuffles), rendering nursing difficult. The coryza may in some cases be preceded by singultus lasting ten or twenty days (Carini), and ulcers may form in the nose, leading to necrosis of the bones and producing at last a sunken and deformed nose which is highly significant. The coryza may extend to the middle ear and cause otitis media, with deafness and otorrhea as the chief symptoms. The *skull* may approach the natiform in shape, and the signs of diaphyso-epiphyseal inflammation develop.

The *cutaneous symptoms* appear early. The skin has a tawny hue, and an erythematous eruption of the nates and genitals is frequently seen; this is patchy, with well-defined margins, and has the characteristic coppery color. In the same localities papules may appear, while pemphigus may attack the palms and soles. Syphilitic onychia may be present, and the lips and angles of the mouth often show fissures that are of real diagnostic worth. Other symptoms are ulcerations of the skin and mucous surfaces, falling of the hair, and a moderate glandular enlargement.

Enlargement of the spleen is a frequent characteristic symptom, and, according to White and Martin,³ of greatest importance "when noticed

¹ With prenatal syphilis we are not concerned.

² *Vererbung der Syphilis*, Vienna, 1876.

³ *Genito-urinary and Venereal Diseases*, 5th ed., 1902.

early—the first three months after birth—since at this period enlargement of the spleen due to rachitis can hardly come into question.”

Swelling of the liver may also be present, but is of little diagnostic import. Syphilitic infants occasionally manifest a hemorrhagic tendency. At birth bleeding from the umbilicus may occur; later, into the subcutaneous tissue and from the mucous membranes (gastro-intestinal, vaginal, nasal, etc.). Hecker¹ considers an examination of the umbilical cord important for the early recognition of syphilis in the offspring of syphilitic parents; if the microscope shows characteristic changes, time may be gained for treatment; “these changes range from a decided endarteritis or periarteritis or phlebitis to a simple round-celled infiltration of the blood-vessel walls or the surrounding tissue.” As pointed out by Osler, these cases must not be confounded with Winckel's disease.

Among *nervous symptoms*, restlessness, sleeplessness, and a harsh, shrill cry which may be almost constant for days together and due most probably to darting pains, are the chief. Anemia and other evidences of syphilitic cachexia soon supervene.

(3) **Late Symptoms.**—The symptoms of syphilis hereditaria tarda may be arranged in groups (Fournier):

(1) *Those Indicated by the General Appearance.*—There is a retarded general development, as shown by the small stature, undeveloped muscles, the graceful form, and infantile appearance at ages varying from four to twelve or more years. The skin has an earthen tint, and the hair may be scanty and late in its appearance on the face and genitals.

(2) *Skin-cicatrices.*—Cutaneous scars, particularly if multiple and extending over a circumscribed area, are important diagnostic signs. Their form is usually round or serpiginous, and their chief location the mouth, nose, soft palate, and lumbo-gluteal regions.

(3) *Lesions of the Skeleton.*—The natiform skull, “with a transverse enlargement, lateral bulgings, and the flattening in the middle,” is almost pathognomonic. Asymmetric and hydrocephalic skulls are also to be considered, in many cases, as signs of hereditary syphilis, as is a sunken and deformed nose. The thickened, “sabre-shaped” tibia, due to gummatous periostitis, is capital evidence of the disease, while the chicken-breasted thorax is significant.

(4) The *testicles* show an arrest in development (infantile testicles). This is a sclerotic atrophy.

(5) *Hutchinson's triad*, under which title come (a) the Hutchinson teeth; (b) ear-conditions; (c) affections of the eye.

(a) *The Hutchinson Teeth.*—The teeth may be late in appearing, and the dental arch may be malformed, the teeth presenting various irregularities in form and condition (dental dystrophy).

The incisors, especially the superior median of the second dentition, are notched, and show a thinness of the free edge, an atrophy of the summit, and crescent-shaped erosions. Fournier² calls attention to the absence of one, two, or more teeth in a great number of cases.

(b) *Ear-conditions.*—Otorrhea, secondary to naso-pharyngeal catarrh, has already been mentioned, and, in addition, at or about the time of puberty an incurable form of deafness may develop speedily, without the presence of pathologic lesions to explain the same.

¹ *Jahr. f. Kinderh.*, Bd. li, Heft 3.

² *Gaz. hebdom. de méd. et de chir.*, January 18, 1900.

(c) *Affections of the Eye*.—These are interstitial keratitis and iritis, affecting both eyes successively.

VISCERAL SYPHILIS.

Syphilis of the Brain and Cord.—**Pathology.**—The most characteristic and not infrequent lesions are: (1) *Diffuse Gummatus Meningitis*.—This occurs most often in the pia, extending to either the dura or brain-substance. It is seen as patches of round-cell infiltration with sclerosis of the blood-vessels. In the cord the same changes are found.

(2) *Gummata*.—Their usual situation is in the membranes, more often the dura, extending to the brain secondarily. Rarely the brain-substance only is affected. Their size varies from that of a millet-seed to that of an egg, and they present irregular contours. They are single or multiple and are usually situated either in the cerebral hemispheres or on the pons, and rather superficially, connecting directly or indirectly with the dura or pia mater. In gummata of average size a cut-section shows caseation in spots which are connected and surrounded by firm, translucent, gray or reddish-gray, fibrous tissue; and, according to Gowers, the more irregular surfaces and the irregular caseation serve as important distinctions from tuberculous tumors. When, as is usual, the gummata touch the membranes, meningitis—subacute or chronic, with much thickening—is combined. Gummatus growths may attack the cord. They seldom attain to a large size. In a case reported by Osler a new growth, from three-eighths to one-fourth of an inch in diameter, occupied the cord opposite the fourth cervical nerve.

(3) *Endarteritis*.—This important lesion of syphilis may result in aneurism, hemorrhage, or narrowing and obliteration of the lumen of the blood-vessels. As a consequence of the latter, areas of softening and secondary degeneration occur, varying in size with the distribution of the affected vessel. Cerebral thrombosis may be found. Similar vascular lesions occur in the cord.

Etiology.—Cerebral syphilis is usually a late (tertiary) manifestation, appearing on the average three or four years after infection. After twenty years it is rare. Taylor¹ has pointed out that syphilis of the nervous system is likely to appear in persons of a neurotic or neurasthenic constitution, particularly in those cases where the treatment required for the secondary period of the disease has been neglected or insufficiently carried out.

Symptomatology.—*Imbecility* and *idiocy* may be due to inherited syphilis, but they are probably too often attributed to this cause. The other features simulate those of the acquired form.

The symptoms of the acquired form are with few exceptions referable to three affections: (a) epilepsy, (b) brain-tumor, and (c) paralysis.

(a) *Epilepsy* coming on after the twenty-fifth year, not dependent upon alcohol nor uremia, is usually due to the ravages of syphilis, and a careful search for traces of scars and of the entire body-surface for bone-lesions, etc., should be instituted. The appearance of the disease may be preceded by psychic disturbance, headache, dizziness, and loss of memory. Hysterical manifestations may also be presented, being

¹ R. W. Taylor, *Venereal Diseases*.

probably provoked by the specific lesions. On the other hand, a protracted torpor which may last for a few days or as many weeks may develop. In one of my own cases periods of marked mental excitement, that persisted for three or four days, alternated with periods of almost complete insensibility of about equal duration.

(b) *Brain-tumor*.—The symptoms pointing to brain-tumor will be discussed under this head in the section on Nervous Diseases. The syphilitic nature of the cerebral growth cannot be determined with any degree of certainty except in the presence of a clear history of syphilis—congenital or acquired—and the characteristic symptoms or traces of the primary, secondary, or tertiary lesions. In such cases the diagnosis is almost undoubted.

It must be remembered that the secondaries are either sometimes absent or go unnoticed, and if the patient has had a primary sore, the presence of the characteristic symptoms of brain-tumor (headache, optic neuritis, convulsions, etc.) make the existence of specific nerve-lesions highly probable. The chancre may also be overlooked or denied, and it is in such instances as the latter that the occurrence of convulsions in persons over thirty should excite suspicion.

(c) *Paralysis*.—This may take the form of hemiplegia (due to cerebral hemorrhage or gumma) or of general paralysis (*dementia paralytica*). The relation that these affections bear to syphilis will be indicated in its appropriate place in this work in the description of Nervous Diseases. The fact may here be pointed out that syphilis may induce precisely the same changes met with in general paralysis of the insane.

The history of syphilitic infection, together with symptoms of an *atypical* type of spinal tumor, points to *gumma* of the cord. Syphilitic myelitis usually develops in five years after the infection, and may pursue an acute or subacute course, though oftener it takes the form of chronic myelitis. The latter attacks by preference the lumbo-dorsal section of the cord—a fact corroborated by the character of the symptoms. The clinical features, however, are not distinctively syphilitic; and the process is uninfluenced by the most vigorous antisymphilitic measures. When the etiologic influence of syphilis can be shown, the diagnosis of syphilitic myelitis rests upon more certain ground. Acute syphilitic myelitis gives an unfavorable prognosis.

General Diagnosis.—The onset in nervous syphilis may be acute or subacute, and the symptom-complex embraces a multiplicity of phenomena, there being an especially erratic distribution of the ocular and other attending palsies and early marked impairment of the mind, all occurring, as a rule, in *early adult life*.

SYPHILIS OF THE LIVER.

In my experience the liver, with comparative frequency, bears the stress of visceral syphilis. Syphilis of the liver occurs more frequently in men than in women, and, according to Peiser,¹ appears most frequently in from five to fifteen years after date of infection.

Pathology.—The lesions may be thus classified: (a) **Diffuse Syphilitic Hepatitis**.—This is met with chiefly in congenital cases. Though

¹ *Die Leber syphilis brochure*, Leipsic, 1886.

its occurrence in adult life has been questioned by some, I have seen an instance in an adult who died of cerebral hemorrhage. The liver is uniformly enlarged, firm, and resists the cutting-knife. Its color is grayish-yellow.

The microscope shows a marked increase in the connective tissue and a cell-infiltration throughout. From intense, focal cellular infiltration miliary gummata may result; these undergo contraction, diminishing somewhat the size and altering the shape of the organ.

(b) **Gummata**.—These may be seen in congenital cases (chiefly the miliary gummata). As seen in the adult, hepatic gummata are disseminated nodules, with the usual central, cheesy mass surrounded by a zone of grayish fibrous tissue and varying in size from a hazlenut to an apple. They form separate tumors, whose favorite seats are the convex surface of the organ, especially near to the suspensory ligament, and in the region of the portal vessels. They are usually tertiary lesions, and do not appear until a number of years (two, three, or four) after infection. These so-called syphilomata in the advanced stage contract, and the liver will be found smaller than the normal. Deep furrows due to contracting fibrous bands traverse the organ in different directions and divide it into lobes of various dimensions. Gummata frequently undergo fibroid change, but more rarely they soften and liquefy (Wilks). On the other hand, before contraction occurs the liver is increased in size and the gummata form protuberances on its surface.

(c) **Gummatous Arteritis**.—Briefly, this may affect both the portal vein and hepatic artery, though syphilitic endarteritis is situated chiefly in the smaller branches of the latter.

(d) **Perihepatitis**.—Here Glisson's capsule is thickened, owing to augmentation of its connective-tissue elements. From the latter there dip into the hepatic tissue cicatricial bands, particularly along the portal canals, which may change somewhat the shape of the organ. Section shows admirably the pale scar-like tissue (*vide* Diseases of the Liver).

Clinical History.—The affection may exist without symptoms. In the *congenital form*, however, we have signs of hepatic enlargement, with icterus, the spleen being likewise large and firm, as a rule. The history and associated lesions are necessary to a certain diagnosis.

In the *adult syphilis* of the liver does not usually attract attention until the gummata interfere with the portal circulation. As they undergo contraction they tend to occlude some of the portal branches, or they may, on account of their situation, exert pressure upon the vena porta itself. In either event the evidences (ascites and splenic enlargement) of portal obstruction will develop as in alcoholic cirrhosis. The gastro-intestinal symptoms common to the latter disorder are also present, and obstructive jaundice may supervene, though it is, comparatively speaking, rare. Pain, usually localized to some particular spot over the right hypochondrium, is sometimes complained of, and may be quite severe, while pressure over the painful area elicits great tenderness.

Physical Examination.—In the early stage, while the organ is enlarged, flattened, irregular protuberances may be detected by the palpating fingers. At a more advanced period ascites may interfere with palpation, and in such cases an aspiration of the fluid will enable one

to feel the syphilomata. Finally, in the stage of contraction the results of palpation are obviously negative.

There is a group of cases in which the clinical picture is that of *advanced amyloid disease* of the viscera. The liver and spleen are enlarged, the urine is increased in amount and contains albumin and tube-casts, and finally dropsy supervenes.

Diagnosis.—This rests upon the etiology, the presence of scars on the skin-surface, bone-lesions (especially irregularities of the tibial surfaces), or other evidences of the ravages of the disease, and upon moderately good general health. The most important local symptoms are the hemispheric prominences on the surface of the liver and the localized pain.

The diagnosis between syphilitic disease of the liver and *echinococcus-cysts* is sometimes extremely difficult. R. Lennhoff has noted in a number of cases of echinococcus-cyst that on deep inspiration a furrow forms above the tumor, between it and the edge of the ribs.

The clinical findings resemble those of cancer of the organ. I have contrasted the main dissimilar points in the subjoined table:

SYPHILIS OF THE LIVER.

CANCER.

| | |
|---|--|
| History of heredity or of infection. | History of heredity or of primary growth. |
| Occurs congenitally, or, if acquired, at any age. | Never congenital. Usually occurs after the age of forty. |
| Often accompanied by symptoms of tertiary syphilis—alopecia, rupia, etc. | Often preceded by the primary growth pylorus, uterus, mammary gland. |
| Jaundice and ascites are common, especially the latter. No cachexia. | Jaundice and ascites are rare. Marked cachexia. |
| The margin, on palpation, is markedly irregular, and neither nodular nor umbilicated. | Often the margin reveals the presence of umbilicated nodules. |
| Recovery may follow, or the affection may last for years. | Always fatal. Duration usually from a few months to a year. |

The course and the *results* of antisyphilitic treatment are of value from a diagnostic view-point. The course is slow and often interrupted, while appropriate treatment may lead to recovery, as in three of my cases.

SYPHILIS OF THE ALIMENTARY TRACT.

The lesions in the mouth have been for the most part considered. In the tongue gummata often develop. A decidedly fissured appearance of the organ and whitish scar-like patches upon the surface may be observed in syphilis, but have no essential connection with that disease. Perforation of the palate, due to tertiary lesions, is not rare. Gummata also appear on the posterior wall of the pharynx and lead to ulceration, which may cause fatal hemorrhage by erosion of adjacent large blood-vessels (internal carotid, etc.). The walls of the esophagus may also be invaded, resulting usually in stenosis.

The stomach-walls may be infiltrated and, rarely, ulcerated. Einhorn, Fournier, and others have met gastric ulcer in syphilis; it was cured by the specific treatment. Syphilitic tumor of the stomach may rarely occur; the symptoms are those of malignant growth, resembling cancer,

but curable. Syphilitic ulcers may appear in the intestines. The condition may lead to perforation and peritonitis; more often to stenosis.

Gummatous infiltration of the rectum is a somewhat frequent, severe, and clinically important affection. It is much more common in women than in men, taking place in the "submucosa above the internal sphincter." It has frequently caused a fatal result in persons who failed to show post-mortem specific lesions in other viscera, and hence it is to be classed as one of the ravages. The result of the gummatous infiltration is the production of a funnel-shaped stenosis of the rectum which narrows from below upward. Above the stenosis, and directly dependent upon it, there is dilatation of the rectum and the descending colon. Here may also be found ulcers—some specific, and others the result of mechanical pressure exerted by the fecal accumulations.

Symptoms.—The clinical features are for the most part those of a gradually induced *stenosis* of the rectum. At first there may be hemorrhages, suggesting internal hemorrhoids. The action of the bowels is irregular, and is followed shortly by a tendency to dysenteric diarrhea, with pains, tenesmus, and scanty stools containing mucus and pus. Prolapse of the rectal mucosa may occur, and, owing to the presence of small hemorrhoids, the true nature of the case may be overlooked. The disease is most distressing, and leads slowly and gradually to extreme emaciation and asthenia. Death may be due to the latter or to some complication (perforative peritonitis, etc.).

Diagnosis.—This may be aided by a clear history of associated syphilitic symptoms or of specific lesions, including amyloid degeneration. In tubercular ulcer other undoubted evidences of tuberculosis are found. Carcinoma is usually situated higher up the rectum than gumma and more often forms firm adhesions to surrounding parts. Final diagnosis would depend on microscopic examination of an excised portion.

SYPHILIS OF THE LUNGS.

While undoubted cases occur, syphilis of the lungs is rare indeed.

Pathology.—The cases are pathologically divisible into three forms: (a) Gummy tumors; (b) Interstitial pneumonia; (c) Fetal pneumonia.

(a) **Gummy Tumors.**—These appear as yellowish-white scattered nodules; varying in size from a cherry-pit to a hen's egg. Their centers are dry and caseous-looking, and their peripheral zones fibrous. They are relatively thicker set near to the root of the lungs. Cicatricial bands may be seen connecting not only the separate nodules, but stretching outward to the thickened pleura. Such growths may undergo softening and ulceration, thus forming a cavity that rarely attains to large measurements; or, on the other hand, in favorable cases the fibroid changes and cicatrization may lead to recovery.

A primary lesion is atrophy of the alveolar walls, with hyaline degeneration of the capillaries (Councilman). Broncho-pneumonia (not distinctively syphilitic) may be associated.

(b) **Interstitial Pneumonia.**—This is a fibrous infiltration, showing a predilection for the right lung. Its chief seat is the root of the lung, whence it extends along the bronchi and vessels, and usually involves a part of one or more lobes. Occasionally its starting-point is the pleura,

from which the process advances along lines corresponding to the interlobular tissue. Bronchiectasis may be noticed. Gummata may also be associated, or may have been present and been practically obliterated during the process of cicatrization. I have seen an instance in which the merest vestige of gummatus material remained.

(c) **Fetal Pneumonia** (*Virchow's White Hepatization*).—This is peculiar to the new-born, in which miliary gummata first occur, followed by hepatization of large zones or an entire lung. The chief changes are an infiltration of the alveolar walls, while the air-cells are filled with desquamated epithelium; on section the tissue presents a grayish-white appearance.

Symptoms.—From what has just been stated it is clear that a certain limited number of cases present symptoms and signs that simulate ordinary ulcerative phthisis, but do not show bacilli in the sputum, and hence have no connection with genuine phthisis. There is another group of cases in which the picture presented to view is almost identical with that of fibroid induration though usually giving a distinctly syphilitic history. I am not prepared to say that there is an acute syphilitic broncho-pneumonia analogous to acute pneumonic phthisis, though I fail to see any reason why malignant syphilis may not attack the lung and take that form. The symptoms may be too few and too mild to afford ground for suspicion.

Diagnosis.—If a suspected case is treated early, the result may serve to corroborate the diagnosis, which is at first far from being final.

Bronchiectasis, dependent upon syphilitic peribronchitis or interstitial pneumonia, cannot be discriminated from other forms of that disease except there be a clear history of infection, and unless associated scars or active syphilitic lesions coexist. *Pulmonary tuberculosis* cannot be distinguished from *pulmonary syphilis* without a careful microscopic examination of the sputum. Moreover, it must not be forgotten that luetics often develop ulcerative phthisis, and hence these affections are often combined. The suspicion of syphilis should always attach to lesions beginning in the lower parts of the lung, and slowly progressing without the production of fever (Taylor).

SYPHILIS OF THE SPLEEN.

Pathologically, syphilis of the spleen is to be classed with the general adenopathy of the disease. According to the statistics of Sée (relating to hereditary syphilis) and of Avanzini and Schuchter (relating to acquired syphilis), in about 25 per cent. of the cases of secondary syphilis hypertrophy of the spleen may be noted. This augmentation begins from two to four weeks after the appearance of the chancre, and gradually increases, persisting throughout the secondary period; it is not, however, observed during tertiary stage. It is often accompanied by localized pain—syphilitic pleurodynia (Besnier). Gummata are rare.

SYPHILIS OF THE CIRCULATORY SYSTEM.

The Heart.—The pathologic divisions are—(a) *Gummata*, which attack chiefly the walls of the left ventricle. They are usually encysted.

(b) *A Fibro-sclerotic Myocarditis*.—The process begins in the peri-

vascular tissue and proceeds from the vessel walls outward (Mracek). It is diffuse, as a rule, and leads to narrowing of the lumina of the coronary arteries and their branches or to aneurysmal bulgings, but the pathologic effects of these lesions are seldom detected clinically. Sudden death may occur.

(c) *Syphilitic Endocarditis*.—The changes are of the fibro-sclerotic variety, and not of the more acute verrucose or warty type. The symptoms to which the lesion gives rise are depicted under Organic Valvular Disease.

SYPHILIS OF THE ARTERIES.

Two forms are recognized: (a) *Obliterating Endarteritis*.—Here the syphilitic product consists chiefly of proliferated subendothelial tissue, which encroaches more and more upon the lumen of the vessel—a fact to which the disease owes its name. This so-called “Heubner’s degeneration” is not peculiar to syphilis, but, as Osler says, “if, however, there are gummata in other parts, or if there be gummatous periarteritis in adjacent vessels, the process may be regarded as syphilitic.

(b) *Gummatous Periarteritis*.—The arteries most frequently involved are those at the base of the brain. Charcot describes a condition which he calls “syphilitic periarteritis,” where the tunics of the arteries are infiltrated with tumors or nodosities which the microscope showed were the result of an acute arteritis producing infiltration of connective-tissue cells into the tunica media.

Syphilis of the arteries has an important etiologic bearing upon atheroma and aneurysm (*vide* Diseases of the Arteries).

SYPHILIS OF THE KIDNEYS.

Renal syphilis belongs chiefly to the tertiary stage, though it may appear in the secondary.

Pathology.—(a) *Amyloid degeneration* is a common renal lesion.

(b) *Chronic interstitial nephritis*.

(c) *Gumma*.

Symptoms.—Except in the case of amyloid degeneration the conditions are impossible of correct diagnosis. Wagner describes a special form which he calls *acute syphilitic glomerulo-nephritis*. Clinically, it is characterized chiefly by hematuria, and ends rapidly with uremia.

SYPHILIS OF THE JOINTS.

The following division of the affection is made by Hutchinson of London:

(1) *Synovitis* appears during the secondary stage, but soon clears away under appropriate treatment, leaving no traces behind.

(2) *Perisynovial gummata*.

(3) *Arthritis*, due to osseous nodes or gummata in the neighborhood of the joints.

(4) *True Chronic Synovitis*.—This is the most common form of syphilitic arthritis.

(5) *Syphilitic chondro-arthritis* (Virchow).

The last four forms belong to the tertiary lesions.

Symptoms.—It is to be borne in mind that a joint-affection that does not yield to specific treatment is not necessarily non-syphilitic.

Perisynovial gumma attacks frequently the tissues around the knee-joint; it is very chronic in its course and is more common in women.

Arthritis due to osseous nodes has a special diagnostic feature in the severe nocturnal pains. The fourth form of syphilitic arthritis (true chronic) is the most common among the types due to acquired syphilis, while the symmetric synovitis of the knees occurring about puberty is perhaps peculiar to the congenital cases.

SYPHILIS OF THE TESTICLES.

The lesions are of two forms: (a) *Gummata*.—These produce hard, usually nodular, swellings, either single or multiple, and of moderate size, that occupy the substance of the testicle and sometimes the epididymis.

(b) *Interstitial Orchitis*.—This is a fibro-sclerotic change that leads to slow, gradual atrophy. Though bilateral, it is usually more marked on one side than the other. *Epididymitis* occasionally develops as a late secondary lesion. It is usually unilateral, painless, and quickly disappears under treatment. In the tertiary stage gummata may develop.

Diagnosis.—In gummatus orchitis the swelling of the testicle is painless, smooth, globular, dense, and heavy, with no tendency to involvement or ulceration of the overlying skin.

In *tuberculous disease* the history and associated lesions differ from those of syphilitic orchitis, and the head of the epididymis is generally affected. Atrophied testicles may be due to congenital syphilis. In such instances typical scars, eye-affections, and the characteristic physiognomy are usually to be noted. Hydrocele may owe its origin to the same cause. Atrophy of the testes may lead to impotency and sterility. Such instances are not to be mistaken for the results of metastasis in *mumps*.

General Diagnosis of Syphilis.—Perhaps sufficient has been said regarding the importance of obtaining a correct statement with reference to the primary infection. On failure to find evidence of a genital chancre, an examination for extragenital primary sores must be instituted, even among children. The *treponema pallidum* may be obtained from the serum of the tonsil in from 80 to 90 per cent. of patients suffering from secondary untreated syphilis (Campbell).¹

The striking characteristics of the cutaneous manifestations of secondary syphilis are, first, symmetrical distribution; second, polymorphous character; third, non-inflammatory nature, and fourth, raw-ham or dark red color. In this connection two facts need to be emphasized, first, that a syphilitic eruption, either macular or papular, never causes troublesome itching; and second, that a patient with a syphilitic eruption may experience itching due to another cause—namely, eczema or scabies.

Inherited syphilis may be diagnosticated on the appearance in a child under five months of snuffles and the characteristic skin-eruptions. *Syphilis hereditaria tarda* may be recognized either from a retrospective view or from the presence of active lesions and symptoms.

¹ *Jour. Amer. Med. Assoc.*, May 14, 1910.

Tertiary manifestations of acquired syphilis embrace these points: 1. The consideration of the fact that obscure cases in general and atypical symptom-groups are often due to the syphilitic taint. 2. Direct information or proof, as the result of careful inquiry, to show that the primary and secondary stages (either one or other, or both) have transpired. 3. The evidence presented by the patient and to be obtained by the careful objective examination of the eyes (for iritic adhesions, etc.), throat and skin (for scars), bones (for necrosis and nodes), and the testes. 4. Certain symptoms are significant, such as nocturnal pains, paralysis of the single cranial nerves, double deafness without otorrhea, etc. 5. The therapeutic test may aid in doubtful cases.

The presence of scars constitutes a most important factor in making a retrospective diagnosis. Recent scars are pigmented, and exhibit a slow, progressive clearing up, until, from four to eight years after infection, they are wholly decolorized, pearly white in color, and smooth. On the other hand, as pointed out by Hyde, eczemato-varicose scars remain stationary. These scars are apt to be found on the scalp and on the anterior surfaces of the legs. They may be single or multiple, and may exhibit certain defined shapes (semilunar, dumb-bell, etc.).

Justus's blood-test for syphilis, which consists in a sharp, transient reduction of the hemoglobin after the administration by inunction or hypodermic injections of mercury, is not pathognomonic, but an aid in diagnosis. It occurs in conditions other than syphilis (Christian and Foerster).¹ Both inherited and acquired syphilis can now be recognized by the serum reactions of Wassermann and Klausner—in from 90 to 95 per cent., according to Butler.² Obviously, the Wassermann reaction is of the greatest necessity and diagnostic importance in cases in which syphilis is not recognizable by the ordinary methods of examination—*e. g.*, cerebral or spinal syphilis, syphilis of bones and the internal organs. The reaction being a systemic one, it follows that it is indicative only of the presence of active syphilis. On the other hand, a negative Wassermann reaction does not imply that the *treponemæ* are absent in lesions of a fibrous character, but may mean their temporary disappearance from the lymphatic and vascular structures. It is clear that treatment should not be discontinued simply because the Wassermann reaction is negative.³

General Differential Diagnosis.—Numerous affections and conditions—local and general—are liable to be confounded with syphilis. Mere allusion to some of these common errors of diagnosis can be made here, while others must be omitted altogether:

(a) *The primary sore* of the lip has been mistaken repeatedly for cancer. The history and symptoms of syphilis, together with the therapeutic test, must clear up the doubt.

(b) Certain *skin-eruptions* (lichen, psoriasis, papular eczema, measles, etc.) may be mistaken for the eruption of secondary syphilis. J. V. Shoemaker⁴ details the differential diagnosis in a recent article, which the reader who desires full information may consult.

(c) Care must be exercised lest the *specific eruptive fevers*, especially the pustular stage of small-pox, be mistaken for secondary syphilis.

¹ *Univ. Med. Mag.*, Nov., 1895.

² *Jour. Amer. Med. Assoc.*, Sept. 5, 1908.

³ Wassermann's reaction is quite complicated, and for the details of the method itself, the reader must consult special works on diagnosis.

⁴ *Medical Bulletin*, November, 1893.

(d) The syphilitic arthritis which may develop at the onset of the second stage must be discriminated from *rheumatic arthritis*—an easy task if only the attention be drawn to the primary lesion and the characteristic secondaries in cases of the former disease.

(e) Syphilis in the tertiary stage may simulate *chronic gout* or *rheumatism*, and unless there is definite evidence of syphilis on the one hand, or typical rheumatic symptoms and history on the other, the diagnosis may remain indefinitely uncertain. The therapeutic test may aid.

(f) *Periosteal nodes*, like those occurring in syphilis, may follow vaccination, small-pox, typhus and typhoid fevers. Here the history and associated phenomena furnish reliable data for discrimination.

(g) *Carcinoma of the tonsil* has often been diagnosed, and the tonsils have been excised when really the seat of a syphilitic lesion.

(h) Janeway¹ asserts that *chronic syphilitic fever* and *tuberculosis* are not rarely confounded.

Treatment.—(a) **Prophylaxis.**—To prevent the transmission of hereditary syphilis infected persons should not marry within four years after the appearance of the primary sore. "Marriage should also be prevented when the patients have not been subjected to a thorough and prolonged treatment" (Porter). If at the end of the third year the patient presents a mucous patch, he must wait one year longer.

A healthy mother may safely be allowed to nurse her syphilitic child owing to her acquired immunity (Colle's law). Should she be unable to suckle the child its prospect of survival is greatly diminished. Wet-nurses should not be employed for syphilitic children, but may be for non-syphilitic, even when the mother is affected. If syphilis appear in the mother during pregnancy, antiluetic treatment should be begun and persisted in even after apparent recovery. After the birth of the child treatment should be continued, if the child be nursed by the mother, with a view to medicating the milk.

As has already been stated, the most frequent mode of infection is irregular and illicit sexual congress, and it follows that absolute moral purity would go further toward the prevention of this widespread malady than any sanitary code or legal restrictions. Physicians cannot too strongly advocate continence. Should prostitution be regulated and controlled by the state? Experience has shown that but a slight control is exercised over the spread of syphilis in countries where systematic regulation of prostitution is attempted by the state. I am of opinion that the state should maintain some form of sanitary regulation and control, but, unfortunately, to render this efficient demands that prostitutes shall be officially registered. Such a sanitary supervision should consist in the examination of every prostitute at least twice a week, including a microscopic examination of the uterine and vaginal secretions, and the sending of every diseased prostitute to a hospital with a special department for such cases.² Palmer suggests that the female offender is usually not aware of the existence of a primary sore, while the male is; hence the latter should undergo inspection also. Inspection of prostitutes, however, unless rigid and careful, is absolutely valueless. Chancres are often concealed from view in the vagina or upon the lateral aspect of the

¹ *American Journal of the Medical Sciences*, September, 1898.

² *The Berlin Commission on the Prevention of Syphilis*, Dec. 1, 1892.

os uteri. The maintenance of legal brothels, however, is not here recommended, either from a moral or hygienic standpoint. Experiments have shown that the application of calomel ointment within an hour of inoculation is preventive of infection in man (Metchnikoff and Roux).

(b) **Medicinal Treatment of Hereditary Syphilis.**—For syphilis of the new-born, mercury by inunction or in the form of calomel (gr. $\frac{1}{10}$ —0.064, t. i. d.) or gray powder (gr. $\frac{1}{2}$ —0.0324, t. i. d.), is to be employed. If these babies must be hand-fed the issue is almost unexceptionally bad.

When the first symptoms appear at the second or third month the above method of treatment is generally successful. Among the poorer classes no objection is made to mercurial inunctions, and these are often preferable. The ointment may be rubbed into the armpits, thighs, or sides of the abdomen, which should be covered with a flannel roller. The parts must be kept clean; and the mouth washed after nursing with a 2 per cent. solution of boric acid. Shaw prefers to treat infantile syphilis by inunctions, because of the digestive disturbances usually following the internal administration of mercury to children. *Syphilis hereditaria tarda* is best treated by the use of potassium or sodium iodid. To the iodid may be added mercuric chlorid in suitable doses, though the latter may sometimes disagree (Roberts). In addition to the specific therapy, tonic measures are usually indicated.

(c) **Treatment of Acquired Syphilis.**—There is a specific plan of treatment which should be commenced as soon as the appearance of the secondaries has set the diagnosis of the given case at rest. This is the use of mercury, and rarely of potassium iodid also. The instances in which the latter alone is to be administered are rare. Fournier's "chronic intermittent treatment" of syphilis—which consists in continuous medication for two or three years with mercury and iodine alternately—is warmly advocated by some syphilographers; but the continuous mode is, in the opinion of most specialists, of greater advantage to the patient. Unless mercury disagrees or the patient is exceedingly susceptible to its physiologic effects, I use it persistently during the secondaries, and later at intervals until the end of two years. It is a protracted course, and a protracted course only, of the specific treatment that suffices if we would obviate the dread ravages that otherwise are so apt to appear. I usually employ the protiodid (gr. $\frac{1}{8}$ — $\frac{1}{3}$ —0.008–0.021, three times a day), and later the biniodid (gr. $\frac{1}{30}$ — $\frac{1}{24}$ —0.0021–0.0027, three times a day). We should begin by giving one pill three times daily, and increasing one pill each day until the premonitory symptoms of ptyalism appear (tenderness when the teeth are knocked together, and ropy saliva); then the pills should be reduced $\frac{1}{2}$ or $\frac{1}{3}$, depending upon the number taken. By this procedure the physician is able to ascertain for each case the largest dose of mercury that can be given without harm. Hutchinson recommends the gray powder given in pill-form, combined with Dover's powder (*āā* gr. j—0.0648), this pill to be taken from four to six times daily. A well-known mixture, prescribed in dispensaries, contains mercuric chlorid and potassium iodid in combination.

Inunctions of mercurial ointment (3ss—2.0, night and morning) produce excellent results, and it is advisable in cases in which the syphilids yield unsatisfactorily to internal dosage to suspend the latter at intervals of six or eight weeks and give a course of twenty inunctions. White

advances the view that in the later stages, with the involvement of the deeper tissues, the combined use of inunctions over the affected region with potassium iodid internally often seems to have distinct advantages as compared with the administration of the "mixed treatment" by the mouth. It is necessary to omit the inunction once in seven or eight days for one day, and to take a warm bath to aid in the elimination of the mercury.

The hypodermic use of mercury in syphilis is to be adopted only when very prompt action of this agent is desired. Several preparations are used, and whether these are soluble or insoluble is a matter of little moment. The bichlorid takes first place, the dose being gr. $\frac{1}{4}$ (0.0162), in 15 to 20 drops of water, twice a week. Calomel probably holds second place (dose, gr. j—0.0648—in 15 drops of glycerin, twice a week). Among other preparations employed are the albuminate of mercury and gray oil. All injections must be made deeply into the muscles. The subcutaneous injection of sterilized serum from the blood of lambs and calves has been successfully practised by Tommasoli.

The method of fumigation has gained favor in the treatment of syphilis, particularly in institutions on the Continent. Lane recommends that calomel (ziss—6.0) be put in a china bowl about half filled with water; a spirit lamp is placed under this, and the patient, "sitting above it wrapped in a cloak, has a deposit of mercury settle all over his body as the calomel is sublimed." He should remain wrapped in the cloak for one hour, take a fumigation once daily, and remain indoors. From six weeks to three months are necessary to effect a cure.

It is almost universally agreed that the new preparation, "606," offers truly incredible possibilities in the treatment of syphilis, and yet the immense majority of writers are of the opinion that it should not be used in every instance of the disease. The classes of cases in which its employment would appear to be entirely justifiable are—(a) recent cases, in which mercury or iodides have not been used; (b) those in which mercury and iodides have failed; (c) where the Wassermann reaction confirms the diagnosis in suspicious cases, and also where it discloses hidden syphilis. The question of its permanency of curative action has not, as yet, been definitely settled. The effects of the remedy must vary with the stage of the disease, the size of the dose, and its practical methods of administration.

The mode of introduction into the organism is important, and Fordyce states that the order of effectiveness is as follows:

- "1. Intravenous injection of a very dilute alkaline solution.
- "2. Intramuscular injection of an alkaline solution.
- "3. Acid solution (monochlorhydrate or dichlorhydrate).
- "4. Neutral emulsion (intramuscular or subcutaneous)."

The method of injecting the drug in neutral suspension or emulsion subcutaneously gives less permanent results than by the other methods, although it produces the least amount of pain. The technic for 2, or intramuscular injection of an alkaline solution, is as follows: Take a graduated cylinder with ground-glass stopper, add "606" salt; immediately add 15 c.c. hot water, shake vigorously until every particle of the salt is dissolved; then add 2 c.c. normal sodium hydrate (NaOH) solution; a precipitate occurs. Then continue to add sodium hydrate solution in very small quantity, shaking vigorously after each addition,

until the solution begins to clear; then drop by drop, until we have a clear solution. This should be neutral or slightly alkaline; if the cylinder does not contain 20 c.c. of solution, sterile water is added up to that amount. Then 10 c.c. of this solution is injected deep into the buttocks on either side, always taking care to cleanse the parts with soap, water, and iodine.

The intravenous method gives the most satisfactory results and the preparation of the solution employed follows: "Into a graduate holding 250 c.c. drop 10-20 c.c. of sterilized water. Add the required dose of '606,' and mix thoroughly until there is a clear solution; add sterile water or, better, normal salt solution to the 100 c.c. mark; then add pro 0.1 of '606,' 0.7 of normal sodium hydroxid solution, and mix thoroughly until the precipitate is thoroughly redissolved. If after thorough mixture the solution is not clear, add a few drops of the sodium hydroxid solution to produce this, and then add sufficient normal salt solution to make 200-250 c.c. The fluids used are all to be warm. The alkaline mixture is then ready for injection. The Cassel syringe and apparatus (or the Weintraub) supplied for this purpose are preferable, for by their use the dangers of introducing air are reduced, if the operator continues cautious and follows the directions given in the original paper of Schreiber."¹

The dose to be administered varies, according to different clinicians, from 0.3 to 0.7 gramme subcutaneously or intragluteally, while 0.3 to 0.5 gramme is used intravenously. In cases in which the combined intravenous and subcutaneous or intragluteal methods are employed, as much as 0.9 gramme should be used.

The remedy is contraindicated in organic valvular affections of the heart, advanced arteriosclerosis, locomotor ataxia, non-luetic retinal and optic lesions, chronic Bright's disease, the acute infections (including bronchitis), pulmonary disease (except tuberculosis), and advanced diseases of the brain and cord.

The teeth should be cleaned thrice daily. *Hygiene* plays no mean rôle in the successful management of syphilis. The *diet* must be liberal, though green vegetables and fruits are not to be taken. Alcohol and tobacco are the two great enemies of the luetic.

Auxiliary measures, when other lesions are associated, are important. At present, atoxyl, as a remedy, promises much. If syphilis occur in a tuberculous subject, it is of great value to add the potassium iodid to the mercurial, and, if active tuberculous lesions are present, cod-liver oil and creasote as well. Anemia and debility call for iron and a tonic plan of treatment generally. Attention should be given to the stomach, bowels, kidneys, and other organs. At all times it should be borne in mind that the patient, as well as the disease, is to be treated.

In women the iodids should be suspended during menstruation if the flow of blood is excessive, but not the mercury. Says Mauriac: "During pregnancy specific treatment is well tolerated, and often requires to be pushed to a point a little short of intoxication for the good of both the mother and the child, close watch being kept upon the kidneys, suspending treatment at the first sign of albumin."

(d) **Treatment of Tertiary Syphilis.**—For most tertiary manifestations,

¹ Schreiber, *München. med. Wochenschr.*, 1910, No. 39.

including visceral syphilis, we have a therapeutic specific in potassium iodid. This should be used alone, the inunctions of mercury being added if the iodid fails to produce the desired result. I give the potassium iodid in a saturated solution, one minim being equal to $\frac{3}{4}$ grain of the salt. I use gr. x (0.648) t. i. d. at the first dose, and increase the latter 1 grain (0.0648) each day until the manifestations for which it has been prescribed disappear or iodism is induced. It is best given in milk. In cases showing cerebral symptoms it is to be cautiously used, and it is then my custom to combine the iodid with potassium bromid.

In hepatic syphilis the mercurials are usually combined with iodids from the start, and particularly calomel if there be ascites or jaundice.

In nervous syphilis, especially in the graver forms, I begin with large doses (gr. xx—1.296, three times a day), and augment as above indicated. The limit of doses depends upon the effect produced. I have often found sodium iodid to agree better with the stomach than the potassium salt. Mercury should be administered preferably by inunction in combination with the internal use of the iodids in all forms of nervous syphilis. Among unpleasant effects are coryza, conjunctivitis with edema of the eyelids, salivation, and certain skin-eruptions (erythema, urticaria, etc.). In this form of syphilis the specific treatment is made more effective by attention to hygienic measures—fresh air, appropriate diet, and rest.

SPIRILLOSIS.

(*Febris Recurrens; Relapsing Fever.*)

Definition.—An acute infectious disease caused by the spirillum of Obermeier, and characterized by febrile periods which usually last six days, and are separated by a febrile period of the same duration. Manson suggested the term *spirillosis* for this disease, since “relapsing fever” covers “a number of infections, spread probably by a corresponding number of previously unsuspected ticks or other blood-suckers.”

Historic Note.—The first accurate account of this affection was published in 1739, though it is known to have prevailed in Europe and Ireland prior to that period. During the next century numerous epidemic outbreaks, more or less extensive, occurred, and in 1844 the disease made its first appearance in America at the Philadelphia Hospital, being brought by immigrants from Ireland. Subsequently small groups of cases occurred, and were reported by Flint and others, and in 1869 it prevailed considerably in Philadelphia (where it was studied especially by E. Rhoads and William Pepper) and in other large cities of the country. This was the last appearance of the disease in the United States.

Pathology.—The solid organs of the body present no characteristic anatomic changes, though when death occurs during the febrile period the various viscera (heart, liver, kidneys) are the seat of cloudy swelling, and sometimes of hemorrhagic infarct and extravasation. The *spleen* shows the most constant alterations, being enlarged, but in size it exhibits a great variability. Infarction is frequent, and the lymphoid element of the bone-marrow often shows hyperplasia.

Etiology.—Bacteriology.—In 1873, Obermeier discovered in the blood of patients suffering from relapsing fever a special organism, the *spirillum Obermeieri*, until recently classed with the bacteria, but now placed by Schaudinn and others with the flagellate genus trypanosomata. It is a delicate filamentous organism of spiral form and much elongated, its length equalling four to six times the diameter of a red blood-corpuscle (Fig. 30). Examined under the microscope during a pyretic period, it is seen to exhibit active motion among the blood-cells, this motion being spiral and following the long axis of the organism. It is aërobic, and may best be demonstrated in *dry blood* by staining with Wright's stain. It is apparent in the blood only during the paroxysms, and Dr. Van Dyke

FIG. 30.—Bacillus of relapsing fever (from human blood); $\times 1000$ (Günther).

Carter's careful studies have shown that by inoculation of the blood containing spirillar organisms the disease may be conveyed to new or old subjects. Shortly before the crisis the spirilla disappear from the blood, and are, as a rule, absent during the whole of the succeeding apyrexial period. After death they are found in all the organs, but they have not been cultivated successfully on artificial media.

Predisposing Causes.—Age.—The complaint is most common in young adults between fifteen and twenty-five years.

Sex.—A larger proportion of males than females is affected.

The disease is especially apt to prevail in times of famine, and amid antihygienic surroundings.

Mode of Infection.—Tietin's studies indicate that the medium of transmission may be through suctorial insects (as bedbugs). Mackie¹ observed an epidemic of relapsing fever in which the pediculus corporis played a part in the transmission of the disease. A well-marked percentage of the lice taken from the infected ward contained living and multiplying spirilla. During epidemics nurses and physicians are frequent sufferers, and there is some evidence that the disease may be conveyed by fomites.

Clinical History.—The incubation period ranges in its duration from four to ten days, though sometimes it is even briefer; and in this stage certain symptoms (malaise, fugitive pains) may appear.

The invasion is abrupt, often occurring on awakening in the morning, and commonly the attack is ushered in with a severe rigor, though there may be only a repeated slight shivering. The chief accompanying symptoms are frontal headache, vertigo, severe pains in the loins and limbs, and marked prostration. The temperature rises soon, and often rapidly, reaching 105°–106° F. (41.1° C.) on the first or second day. The skin is dry and pungent, and presents very soon either a "characteristic dirty-yellow color" or a distinctly bronzed appearance. The cheeks are flushed,

¹ *British Medical Journal*, Dec. 14, 1907.

the eyes sunken, and profuse perspiration often takes place, in consequence of which sudamina are frequently observed. Other forms of eruption have been described, but none that are either constant or characteristic. In certain epidemics *herpes labialis* has been noticed. At first the *tongue* is moist and coated with a yellowish-white fur, and later it may become brown, dry, and fissured, with sordes on the teeth. *Ulcerative stomatitis* has been observed occasionally, and catarrhal pharyngitis and mild tonsillitis may be evidenced by pain on swallowing. Among the *earlier* symptoms are excessive thirst, anorexia, nausea, and vomiting. The vomitus may be yellowish-green, green, or even black in color, and consists partly of bile (rarely, also, blood) and gastric secretions. Constipation often precedes invasion, and is apt to continue throughout the attack.

The *pulse* rises rapidly with the temperature, though the normal ratio between the two is not maintained. The pulse is full and strong, and its beats number from 100 to 140 or more per minute; but in serious cases it becomes weak, irregular, or even intermittent, while at the same time the heart-sounds grow more and more indistinct. Hemic *murmurs* may be audible. The *nervous* manifestations are not of a grave character, but the headache persists, is severe throughout, and the patient is restive and sleepless. Delirium is not common, excepting only in rare cases toward the crisis, and the intellect remains clear, as a rule. The *urine* presents the ordinary febrile characteristics, and may contain albumin and casts. It also contains bile-pigment when jaundice is present. The *respirations* are accelerated, and urgent dyspnea may precede the crisis.

The *physical signs* during the febrile paroxysms are few. The epigastric region and the nerve-trunks are tender to the touch, while the skin-surface and certain muscles are often hyperesthetic. *Palpation* detects a variable degree of enlargement of the spleen and liver, and the signs of bronchitis, of lobular pneumonia, and of hypostatic congestion of the lungs may be present. The symptoms above detailed persist with slight daily fluctuations of temperature until the crisis.

The Crisis.—This occurs from the fifth to the seventh day, and rarely as late as the tenth. It is sometimes heralded by a critical rise of temperature, the mercury touching 108° F. (42.2° C.), but evidenced chiefly by a rapid fall of temperature (within twelve hours) to or below the normal, with profuse sweating. Coincidentally, all other symptoms disappear with marvellous rapidity. The critical sweat may be replaced by diarrhea, intestinal hemorrhage, metrorrhagia or epistaxis, and after the lapse of a day or two the patient expresses himself as being well.

During the *intervals* between the paroxysms the skin may exhibit a faintly jaundiced tint; there may be trivial evening exacerbations of temperature, particularly if complications be present and outlast the fever stage; and the spleen is evidently enlarged. There may be, rarely, but a single paroxysm. As a rule, at the expiration of the second week, a recurrence of all the active symptoms of the primary attack occurs, including the rigor and fever. Quite frequently a third pyrexial stage takes place, and rarely a fourth or even fifth.

The *duration* of the first relapse is briefer than the primary pyretic stage, and if there be subsequent relapses, each succeeding one is separated from its predecessor by the usual apyrexial period, but is briefer

and lighter. Hence, should a fourth or a fifth febrile period occur, it is, as a rule, quite rudimentary. The relative duration and severity of the different febrile periods, and their manner of recurrence, are best appreciated by a glance at the temperature-chart (*vide* Fig. 31).

Complications.—These are not frequent. At the head of the list stands *lobar pneumonia*, and next comes *broncho-pneumonia*, which is always secondary. Rupture of the spleen may occur. Other complica-

FIG. 31.—Temperature-curve of relapsing fever.

tions are septic-pyemic processes, hemorrhagic nephritis, hematuria, iritis, irido-choroiditis, parotitis, laryngitis, entero-colitis, and neuritis. In pregnant women abortion may take place. Epistaxis has been noted, and may prove dangerous. As the result of the very high temperature and toxemia, the heart may become suddenly paralyzed.

Clinical Varieties.—The difference in the general course of cases in different epidemics, and even in the same one, is, for the most part, the direct result of the varying degrees of intensity of the infection. Thus very *light* or even rudimentary cases occur in which the whole course may be made up of one or two brief febrile periods, and their resemblance to ordinary intermittents may be close. The so-called "*bilious typhoid*," which is a form of relapsing fever, occupies the other extremity, being of malignant type. The symptoms are greatly intensified; but more often, perhaps, the condition early merges into a typhoid state, to which are added certain grave features and complications (marked icterus, hematemesis and hemorrhages from other outlets of the body, uremia, sudden collapse, etc.). Septic and pyemic processes, including infarctions, are common accompaniments, and the outcome is frequently unfavorable. Novy and Knapp believe the African form, or tick fever, to be due to the *spirillum duttoni*.

Diagnosis.—The prevalence of an epidemic in which the cases present similar symptoms; the sudden onset; the course and intensity of the fever with its concomitants; the termination by crisis on or about the seventh day; and the peculiar manner of repetition of the fever-

attacks after an afebrile period of equal duration,—are points that distinguish relapsing fever from other affections which simulate it more or less closely. Additional symptoms that are of special value for diagnosis are—enlargement of the spleen and liver, a negative character of the nervous and a prominence of the gastric phenomena, and jaundice. To be able to state that relapsing fever is positively present the *spirocheta Obermeieri* must be found in the blood, and this is particularly true in the earlier cases of an epidemic, before they have passed through their typical relapses. To demonstrate the presence of this parasite in the blood during the fever-stage is not a difficult task. A drop of blood obtained from the finger-tip is to be examined microscopically without previous dilution. On account of their size and motility the spirilla can be readily detected, and usually the attention of the examiner is first arrested by the peculiar joggling movements of the red blood-corpuscles. Then the real disturbing agents appear as slender spirals with a snake-like motion. Their identity may be confirmed by staining with anilin colors, and, in exceptional cases, by injecting them into the blood of the monkey, in whom they produce the disease.

Differential Diagnosis.—*Typhus fever* may be mistaken for relapsing fever, since both have the same predisposing causes, both prevail epidemically, both are characterized by an abrupt onset, with or without prodromes, and by a continued type of fever. In relapsing fever, however, the eyes are clear but hollowed, the cheeks are flushed, and there is a dirty-yellow tint of skin; in typhus the eyes are injected, the pupils contracted, the face wears a stupid, inanimate expression, and the characteristic maculopetechial eruption. In relapsing fever, delirium and stupor are rare, the period of fever briefer, while the blood shows the presence of the spirillum. In typhus relapses are the exception. *Yellow fever* resembles relapsing fever in its general course, but in the former the stage of remission is both briefer and more incomplete. Yellow fever presents a stage of collapse with black vomit, and jaundice is more intense. The spirilla may be detected in the blood, and there is marked splenic enlargement in relapsing fever.

Pel and Ebstein have described a *febrile condition* which sometimes occurs in pseudoleukemia and simulates that of relapsing fever; but it may be distinguished by the absence of the spirilla from the blood, the general enlargement of the lymphatic glands, liver, and spleen, and the fact that the pyrexial periods do not tend to grow shorter.

Prognosis.—The prognosis of relapsing fever is good, but of “bilious typhoid” it is bad indeed. Apart from the type, we must consider, in this as in all other acute infectious disease, the number, character, and frequency of occurrence of the various complications. As stated, these are few, infrequent, and mostly benign. Among those signaling danger are severe hemorrhages (epistaxis, metrorrhagia, hematemesis, etc.), premature labor, signs of uremia and syncope, marked jaundice and excessive vomiting, and urgent diarrhea. Perhaps the most frequent causes of death are pneumonia and acute hemorrhagic nephritis. Individual circumstances render the prognosis more grave—as the want of good nursing, privation, a previously enfeebled system, and old age.

The **duration** depends upon the number of paroxysms, since the latter are of definite length. In the majority of cases there is but one

relapse, and in this event the disease lasts from eighteen to twenty days.

Treatment.—Thorough disinfection and isolation must be carried out in relapsing fever. The general management, including the time and use of stimulants, must be based on the same principles as are employed in typhoid fever. The fever, as well as the nervous and other symptoms, is to be opposed by the cold or gradually cooled bath, employed as indicated in the article on the treatment of the latter disease. Cold spongings, with the ice-cap or the cold pack, may be substituted for the baths in special cases. Internal antipyretics may be reserved for use in cases in which the temperature is very high and the above-mentioned means are impracticable. Small doses of phenacetin (gr. ij to v—0.1296 to 0.3240) or acetanilid (gr. ij to iij—0.1296 to 0.1944) are to be administered, at the same time guarding the heart, and the signs of collapse must be promptly met by the free use of stimulants (strychnin, alcoholics, ammonium, etc.). Vomiting often induces marked debility, and calls for the use of ice or iced champagne and small doses of cocain, morphin, or dilute hydrocyanic acid, preceded by a mercurial laxative. Counter-irritation over the epigastrium is also useful. For the intense muscular pain, restlessness, and sleeplessness nothing is so good as morphin given subcutaneously, and Dover's powder may be employed if the pain be of moderate severity. During the intermissions the patient should be kept indoors for ten days or more, lest exposure or sudden exertion predispose him to a relapse. Solid food may now be gradually resumed, and tonics judiciously given. H. Löwenthal¹ treated 131 cases with antispirechetic serum (obtained from a horse that had been treated with blood containing the spirochetæ) with but 1 death. The treatment of *relapses* differs in no way from that of the first febrile period.

PART III.

CONSTITUTIONAL DISEASES.

DIABETES.

(*Diabetes Mellitus.*)

Definition.—A nutritional affection, attended by an abnormal amount of sugar in the blood, and characterized clinically by persistent glycosuria, by polyuria, and by a progressive loss of flesh and strength.

Pathogenesis.—This is still undetermined. Post-mortem lesions of different organs and structures of the body have been met with in diabetes—a fact that has given rise to a variety of views.

(1) That it is dependent upon *organic disease of the pancreas*, especially granular atrophy, or upon marked functional disturbance of this organ. It has been shown experimentally that extirpation of the pancreas is followed by diabetes, and that if one-half the gland remains glycosuria does not result.

It may safely be assumed that total loss of function always, and partial loss sometimes, leads to diabetes. Lepine and Martz have been able to produce a glycolytic ferment by treating the pancreas after their own special method, which need not be detailed here. It is probable that the pancreas, and particularly the cells forming the islands of Langerhans, furnishes an internal secretion containing a glycolytic ferment. This ferment is identical with that which is contained in the blood, and in the presence of which glycogen is assimilated. Croftan¹ has placed the origin of the blood-ferment in the leukocytes, and believes it, with the pancreatic ferment, to be identical with trypsin.

(2) The *suprarenal glands* have assumed a rôle of much importance since the valuable researches of Herter.² He found that a solution of adrenalin chlorid injected into dogs or painted on their pancreas, caused marked glycosuria. Other reducing substances acted in a similar manner. On the other hand, excision of the left suprarenal gland with ligation of the blood-vessels of the right gland, caused a reduction in the percentage of sugar in the blood. He concludes that “the suprarenal glands make a secretion which is capable of stimulating the pancreas in such a way as to call forth an increased conversion of hepatic glycogen into sugar.” And further “it seems that this disturbance in metab-

¹ *Amer. Jour. Med. Sci.*, April, 1902.

² *Medical News*, October 25, 1902.

olism (glycosuria) is in some way dependent on interference with the oxidative activities of the cells of the pancreatic gland."

(3) If the glycogenic function of the *liver* be interfered with materially, diabetes follows. This may result from organic hepatic disease or a faulty nervous system. Puncture of the floor of the fourth ventricle will also cause glycosuria, and section of the pneumogastric nerve is followed by paralysis of the hepatic vessels, disappearance of glycogen from the liver, and saccharinuria.

(4) The so-called *alimentary glycosuria* has frequently been induced experimentally by Miura and others. It results from the ingestion of more carbohydrates and peptone than can be stored in the liver as glycogen, so that some of the latter finds its way into the hepatic vessels with resulting glycosuria.

(5) The administration of *phloridzin* produces glycosuria both in animals and man. There are two views as to the cause of phloridzin diabetes: (a) that the kidneys, owing to the action of the phloridzin on the renal epithelium, eliminate the sugar from the organism; (b) that an excessive formation of glucose occurs (generally held).

(6) *The Microbic Theory*.—Paul Ernst and others have observed all forms of fungi, but as yet no etiologic relationship has been shown.

(7) Another view regarding diabetes is that the carbohydrates of the food are converted into fat by the protoplasmic action of cells in the intestinal villi, and enter the system in the same way as do fats taken as such. The surplus carbohydrates that escape the action of the cells of the villi are transmuted into glycogen in the liver. The glycogen stored in the liver obviously forms fat also, since this organ has some fat-forming function, and there are thus two barriers preventing the carbohydrate matter from entering into the blood, and if either is deranged, hyperglycemia with consequent glycosuria results.

The influence of the nervous system is undoubted, and Pavy¹ claims that the disease is essentially a neurosis affecting a particular part of the vaso-motor system. In light cases the carbohydrates are not warehoused in the liver and muscles, and the excess of glycogen not burned up in the tissues, so that from the storage reservoirs (liver and muscles) the blood is supplied with an excess of grape sugar. In severe cases the carbohydrate moiety of the proteids of the food or tissues furnishes the sugar excreted in the urine (Stengel).

Pathology.—The *pancreas* in more than one-half the instances shows morbid changes. Opie's² researches, since confirmed by other observers, indicate that the important lesions are those affecting the islands of Langerhans. These peculiar structures appear to have a different function from that possessed by the other pancreatic cells, and are probably the source of the internal secretion of the pancreas. In *chronic interstitial pancreatitis* of the *interlobular* type, the islands of Langerhans are affected only late, and glycosuria is rare. The changes following occlusion of the pancreatic duct by calculus, growths, etc., are of this variety. In the *interacinar* type the cells forming the islands

¹ *Lancet*, May 3, 1906.

² *Jour. of Exper. Med.*, V., No. 4, 1901.

of Langerhans are affected early, hyaline degeneration of the capillaries may be seen, and there is frequent and early glycosuria. In Herter's¹ experiments the injection of fatal doses of adrenalin was followed by granular degeneration of the islands of Langerhans.

Acute necrosis of pancreas, primary cancer, and diffuse cancer may cause glycosuria, but rarely. The *liver* is often enlarged and fatty, particularly the zones corresponding to the distribution of the hepatic artery. According to French writers, there is a diabetic cirrhosis of the organ (*cirrhose pigmentaire*), the pigment being derived from destroyed blood-cells. *Microscopically*, the liver-cells are found to be enlarged, nucleated, and globular in outline. Rindfleisch holds that these changes are most striking in the peripheral portion of the lobule.

The Kidneys.—A well-marked chronic interstitial nephritis, with fatty degeneration, is often present. The tubal epithelium and the vessels of the Malpighian bodies may show a hyaline change. More commonly the appearances are those of an ordinary catarrhal nephritis.

Nervous System.—In rare instances organic disease of the medulla (tumors, sclerosis, etc.) is found. Changes in the posterior columns of the cord have been noted, and a peripheral neuritis, simple or multiple, is commonly seen. The so-called *diabetic tabes* is generally supposed to be due to multiple neuritis.

The Lungs.—The commonest lesions in the lungs are gangrene following pneumonia and the so-called diabetic phthisis. Fatty emboli are found in the pulmonary vessels.

The Heart.—Arterio-sclerosis with cardiac hypertrophy is often met with, but does not constitute a peculiar lesion.

The Skin.—Cutaneous pigmentation (diabetic bronze of the French), more or less uniform, has been reported in 9 cases (Hanot and Chauffard). It is associated with hypertrophic cirrhosis of the liver.

The Stomach.—Dilatation and, according to Jacobson, marked catarrhal changes are common in the early stage.

The Blood.—The normal proportion of sugar in the blood (0.15 per cent.) is usually increased, though there is no immediate connection between the percentage of sugar in the blood and in the urine in diabetes. Both in experimental and pathologic diabetes hyperglycemia may be marked, with moderate or slight glycosuria, and Lépine has shown that diuretics diminish hyperglycemia by increasing the glycosuria. The blood-plasma contains much fat. It is probable that the albuminoid matters in the blood may produce glucose. Glycogen probably exists in the blood-corpuscles, and not in the plasma, "where it would be destroyed by the diastasic ferment" (Dastre), and it is a normal element of the blood, apparently belonging to the leukocytes (Huppert and Czerny.) The alkalinity of the blood is diminished, probably owing to the presence of oxybutyric acid. The corpuscles show no special alterations.

General Etiology.—(a) *Heredity* is generally believed to exert a predisposing influence, since cases are observed to succeed one another in the same family. (b) *Season* also exerts an influence, diabetes appearing more frequently in the months of March, April, July, and Novem-

¹ *Medical News*, May 10, 1902.

ber (Davis). (c) *The male sex* suffers much more frequently than the female. Wegeli, however, found in 107 cases that children of both sexes were affected in an equal proportion. (d) *Age*.—Most cases occur between thirty-five and sixty years of age. Infantile diabetes is rare, and occurs most frequently about the age of five, though it has been met with under one year. (e) *The Hebrew race* is especially susceptible. The colored race rarely suffers, although of a series of 77 cases 8, or 10.3 per cent., were in negroes (Futcher). (f) *The better classes* of society furnish most instances, and particularly that large element composed of neurotic subjects. (g) *A nervous shock* or strain or prolonged mental anxiety acts as a predisposing cause. (h) *Occupation*.—The urine of 607 individuals engaged in manual labor that required great muscular and respiratory activity showed no sugar in any case; while the urine of 100 individuals engaged in intellectual work of a more or less fatiguing character, but always intense and sedentary, showed sugar in 10 of the cases (Worms). (i) *Obesity* predisposes, somewhat, particularly to the lipogenic form. (j) *Certain chronic diseases*—e. g. syphilis, malaria, gout—predispose. (k) *Pregnancy* has a slight though decisive influence. (l) It sometimes follows *acute infectious diseases*. (m) *Locality*.—Diabetes mellitus is, comparatively speaking, rare in America, although Hare's statistics indicate that diabetes is becoming more prevalent. In certain other countries (Normandy, India, France) diabetics appear to be constantly increasing in number, the mortality in Paris having more than doubled from 1883 to 1892, inclusive. The disease is much more frequent in cities than in rural districts. *Contagion*.—Among 770 cases, Senator saw 9 instances of man and wife suffering from the disease. In a series of 5,000 cases 1.8 per cent. of conjugal diabetes occurred (Schram).

Special Etiology.—Under this head may be arranged the following groups of cases: (1) *Diabetes* due to *pancreatic disease*. (2) Cases occasioned by *hepatic disease (organic and functional)*. (3) Those comparatively rare instances caused by *disease of the brain (tumors, sclerosis, or irritative lesions of the diabetic center) and spinal cord*. (4) Diabetes following *traumatism*, and especially injuries to the head. Not infrequently it occurs after injuries to other parts of the body, such as the spine, sacral region, abdomen, etc. In 212 cases of traumatism of the head Higgins and Ogden found 20 cases of glycosuria, though only a small proportion of the cases (2) exhibited a permanent glycosuria. Ebstein,¹ after an exhaustive study of 6 of his own cases and of 44 gathered from literature, concludes that there can be no question of the direct causal relation of traumatic neurosis and diabetes.

Clinical History.—For the sake of accuracy and convenience of description, the cases will be divided into the acute and chronic forms.

1. **Acute Diabetes Mellitus.**—The instances are few and the course is, as a rule, rather subacute than acute, manifesting a predilection for the young and middle-aged. The *onset* is more abrupt than in the chronic form, but the characteristic features do not differ from those of the latter. Many of the cases due to pancreatic disease are of this class. Exceptionally, acute diabetes occurs in the aged.

2. **Chronic Diabetes.**—The symptoms are evolved *slowly and gradu-*

¹ *Deutsche Arch. f. klin. Med.*, April, 1895.

ally, as a rule, and prominent among prodromal conditions is dyspepsia or chronic gastric catarrh. We may note certain nervous disorders, such as headache, mental irritability, moroseness, and insomnia, with or without gastro-intestinal symptoms. The patient may suffer merely from general debility and malaise, and either frequent micturition, polyuria, or unnatural thirst is apt to be noticed. Rarely, diabetes has an *abrupt onset*, as after an injury, a sudden nervous shock, or a chill. With the development of the affection the polyuria and thirst become marked, the appetite keen, and glycosuria appears. In spite of the enormous quantities of food taken, progressive emaciation and debility attend.

Leading Symptoms and Complications in Detail.—(1) *The Urinary Symptoms.*—The daily amount of urine varies from four or five pints to as many gallons. In mild cases and in intercurrent febrile attacks it may be slightly, if at all, increased in quantity. The twenty-four-hour specimen should be examined at once, lest yeast-cells develop and cause the sugar to disappear. Its color is pale and its specific gravity ranges from 1020 to 1050, rarely being as low as 1015; it has an acid reaction, a sweetish, aromatic odor, and a distinctly sweetish taste. Sugar is present, the amount varying from $\frac{1}{2}$ to 1 to 2 per cent. in mild cases, to 5 or even 10 per cent. in severe attacks. The amount eliminated in the twenty-four hours varies from five ounces to a pound or more.

Other forms of sugar than glucose (inosite and levulose) may be contained in the urine, and glycogen has rarely been found. The urine may also contain fermentation-products (acetone, diacetic acid, beta-oxybutyric acid). Acetone strikes a Burgundy-red color on the addition of the chlorid of iron. Hirschfeld's studies upon the excretion of acetone in diabetics show that in severe forms an increased amount is excreted, while other writers regard it as being benign. Diacetic acid is probably of graver significance than acetone, whilst the presence of β -oxybutyric acid is a danger-signal of diabetic coma (*vide infra*).

The *urea* is increased, Kaufman finding it in the blood of diabetic dogs to be doubled. *Uric acid* is either normal in quantity or increased, but a large amount of ammonium is present, indicating an increase of organic acids. The phosphates may also be present in greatly increased proportion (Ralfe), and in such cases the glycosuria may be more or less intermittent. This has been described as a special variety—phosphatic diabetes. Lipuria may be present and creatinin is increased.

Slight albuminuria, often with an intermittent tendency, is common even in the early stages, and is not of grave significance. Well-marked nephritis with its characteristic phenomena may develop, though usually in advanced diabetes; and if albuminuria be marked, the amount of sugar excreted may be considerably diminished. The development of chronic interstitial nephritis, however, is not a favorable complication, as some have supposed. Arteriosclerosis may be observed, and pyelonephritis (rarely) and cystitis (not rarely) may appear as complications. A marked reduction in the percentage of dextrose may accompany the development of intercurrent febrile affections. As the result of fermentative processes in the bladder gases may form (*pneumaturia*).

(2) *Digestive Symptoms.*—Although a general feature, *thirst* may be discussed under this head. This symptom may be most distressing,

necessitating the drinking of large quantities of water at frequent intervals both by night and by day. The amount of water taken stands in direct relation to the amount eliminated. Notwithstanding the fact that the increased amount of water is needed to dissolve the sugar, cases of confirmed diabetes are met with in which thirst is not marked. Cases are also encountered in which the amount of urine is large and the percentage of sugar excreted very low. The cause of the unusual thirst is probably an increased systemic demand for liquids.

The *appetite* is abnormally large and sometimes almost insatiable (bulimia), and there may be an intense craving for carbohydrates. I have, however, met with instances of diabetes in which the appetite was not inordinate. Considering the quantity of food consumed, the digestion is often surprisingly good, but the association of dyspepsia and diabetes is by no means an uncommon one. The stomach may be found enormously dilated at times, yet functioning normally. There is constipation, though brief intervening attacks of diarrhea may occur.

The *tongue* is generally dry, large, often presenting a rough and fissured surface, and it may either be coated or red and glazed. The gums sometimes swell, and may ooze blood. The saliva is scanty and its reaction persistently acid, while the salivary secretion may show sugar on testing. The teeth decay, and aphthous stomatitis or thrush may attack the oral cavity.

The *liver* is frequently somewhat enlarged, though the biliary secretion usually is not disturbed; jaundice may, however, arise as a complication. Marie has given a description of *pigmentary "hypertrophic cirrhosis with diabetes mellitus,"* of which only 9 undoubted cases have been published. It appears late in adult life, and, in addition to the symptoms of diabetes mellitus, slight ascites, considerable hypertrophy of the liver and spleen, with brown or even gray-black cutaneous pigmentation, are among the chief features noted. There is no true icterus as a rule, but the urine is highly colored and contains bile-pigments. Bernoulli¹ reports 41 cases of so-called bronze diabetes.

(3) *Cutaneous Manifestations*.—Diabetic urine, on account of the sugar it contains, has irritant properties, and often produces in the female *pruritus vulvæ*, a troublesome symptom and one that should excite suspicion of this disease. In the male, *balanitis* often occurs, due to the effect of the decomposing urine, and from the same cause the genitals and adjacent cutaneous surfaces may be the seat of *eczema*, particularly in women. General pruritus, due to irritation of sensory nerves by the glycemia, may be observed. The skin is usually harsh and dry, though rarely copious perspiration may be observed, and particularly if phthisis be a complication. The hair often falls off, and in one of my cases *onychia* with shedding of the nails occurred. Among the commonest of the early cutaneous symptoms are *furuncles* and *boils*. Later large *carbuncles* often appear. *Gangrene* (especially of the feet) due to arteriosclerosis is not infrequent, and *edema*, arising independently of nephritis, is not uncommon. Morris has reported 21 cases of *xanthoma diabeticorum*.

(4) *Nervous Symptoms*.—Diabetic coma is the most important symp-

¹ *Correspondenz-Blatt für Schweizer Aerzte*, Basel, July 1, 1910.

tom, marking a fatal termination in more than half the cases. It is of most frequent occurrence in instances showing rapid wasting and in the young, and is heralded by a fruity odor in the exhaled breath and in the urine. The polyuria and glycosuria lessen, while acetonuria increases as a rule. The tolerance for the carbohydrates is increased (Hirschfeld). The cases may be brought under six heads:

Group 1. To this belong abortive forms that terminate in quick recovery. This process may be repeated several times at intervals, and at last a fatal coma may supervene.

Group 2. Perhaps the largest group, in which the diabetic coma follows some form of exhausting exercise. It may end fatally in a few hours or, though less frequently, in three or four days.

Group 3. This is a comparatively small class, and is characterized by collapse of the circulation (small, rapid, feeble pulse, cyanosis, etc.), leading to coma. It is induced either by over-exercise or by intoxication. I have seen 2 typical instances, but feel that it may be questioned whether most of these cases should be classed as diabetic coma.

Group 4. Without previous dyspnea or distress there appear such symptoms as headache and signs of intoxication, and these are followed quickly by deep and fatal coma (Frerichs).

Group 5. Here diabetic coma is preluded by symptoms of some localized disorder, such as gastro-enteritis, pharyngitis, pneumonia, gangrene, or carbuncle. The attack sets in with headache, delirium, distress, and dyspnea both inspiratory and expiratory. Cyanosis may develop early, and, if so, cardiac failure precedes the coma. The duration is from one to five days. This group, which was first described by Frerichs, may have a different onset, and I have seen two fatal cases, one attended by carbuncle, the other with gastric symptoms.

Group 6. Hirschfeld has recently described a class of cases in which we find, in old persons, a moderate glycosuria and coma supervening under the influence of gangrene or carbuncle.

The *causes* of diabetic coma are still obscure. Hirschfeld points to insufficient nutrition from an exclusive meat diet as a factor. Kussmaul believed diabetic coma to be due to acetone. Kulz, Stadelman, and others have more recently found β -oxybutyric acid in the urine, and this is now generally held to be the immediate excitant of diabetic coma (which is an acid-intoxication). This acid results from an increased destruction of the proteids. Lastly, coma must sometimes be of uremic origin, and Herrick¹ emphasizes the fact that casts are very common. Cases that follow suppuration and gangrene may be septic in nature.

Peripheral neuritis is common. The most frequent form is *diabetic tabes*, indicated by an absence of the knee-jerks, darting pains, paresis of the extensors of the foot, and by the peculiar gait (steppage). Other symptoms may be numbness, tingling, and certain trophic disturbances—shedding of the nails and perforating ulcer of the foot. R. T. Williamson found the knee-jerk absent in 25 of 50 cases recorded; and in 18 of 21 cases of diabetic coma. Schupfer² attributed absence of patellar reflex to toxic effects in most cases. Neuralgia

¹ *Jour. Amer. Med. Assoc.*, January 26, 1901.

² *Soc. Lancisiana Roma*, January 24, 1898.

may be a troublesome symptom, particularly when it is of the symmetrical sciatic type, and it points to neuritis. The same is true of paraplegia, a condition that may be met. Herpes zoster may be observed.

Psychopathia (e. g. irritability of temper, hypochondriasis) may sometimes be present, and temporary hemiplegia has been noted.

(5) *Special-sense Symptoms*.—Not infrequently cataract develops, leading to blindness. Its cause is not clear. Transient ptosis and strabismus are seen, and among other ocular conditions are optic-nerve atrophy, iritis, retinitis (often due to associated nephritis), and hemorrhage. Amaurosis is rarely observed. Among the aural symptoms I would mention otalgia, otitis media, and mastoid disease.

(6) *Muscular Symptoms*.—In diabetics there is a tendency to cramps, especially in the calf of the leg, that appears during the night and on waking in the morning. Unschuld found it present in 33 out of 109 cases. Another variety of cramps that may appear at any hour of the day may occur with the so-called "gastric crisis." In these attacks colicky pain in the epigastrium with vomiting and fever attend.

(7) *Respiratory System*.—Serious pulmonary complications may appear in the advanced stages. The most frequent is pulmonary tuberculosis, which has the customary termination, and does not differ from the usual form of the disease. A second, quite frequent complication is gangrene (circumscribed or general). The peculiar offensive odor of the expectoration may be wanting here. A serious form of *pneumonia* (lobar or lobular) sometimes occurs, and may terminate in gangrene.

(8) *Circulatory System*.—The *pulse* may be of natural frequency and tension. In other cases it is somewhat slow, and the tension may be increased; this is often due to an associated arterio-sclerosis. The heart is sometimes quite weak. The rate of the pulse, therefore, varies greatly: it may be slow (bradycardia), not exceeding 40 or 50 beats per minute, or it may be accelerated. Dyspnea, a tendency to syncope, and gastric disturbance may be seen in combination.

(9) *Sexual Symptoms*.—Impotence may be an early symptom; it is often of great diagnostic significance. Diabetes may be acquired during pregnancy: *per contra*, the diabetic may conceive, though rarely, and bear a healthy child; but death of the fœtus occurs in about one-half of the cases. Premature delivery occurs in many cases (26 per cent.). After delivery the condition is generally aggravated.

(10) *Constitutional Symptoms*.—Usually there is a constantly increasing loss of flesh and strength. In the mildest types, however, good bodily nutrition and a fair degree of strength may be maintained. When emaciation is progressive the polyuria is apt to be proportional. The *temperature* is at first normal, later usually subnormal, though intercurrent febrile attacks, due to complications, are often witnessed.

Clinical Varieties.—(a) *Infantile Diabetes*.—Heredity, traumatism, and convalescence from severe acute infectious disease are the chief causes. The type is severer and the course shorter than in adults. A comparatively mild chronic form, however, is rarely met in children.

(b) **Pancreatic Diabetes.**—This is a grave variety, and may present evidences of pancreatic involvement. There may be epigastric pain; the fats are poorly assimilated; and the physical signs may rarely point to pancreatic growth. Fitz noted that out of 166 cases treated in the Massachusetts General Hospital fatty stools were not recorded in any instance. Marked polyuria and great thirst may be absent.

(c) **Alimentary or Lipogenic Glycosuria.**—This is caused by dietetic errors, and especially by excesses in eating and drinking, combined with physical inactivity. Block experimented on 50 patients, and found that the amount of grape-sugar that could be given before glycosuria appeared differed widely in different diseases. Frequently the smallest quantity was required in *nervous diseases*, and particularly in cerebral affections. Von Jaksch induced alimentary glycosuria in cases of hysteria and in cases of phosphorus-poisoning with fatty degeneration of the liver. This form of the disease is often a temporary affair. The percentage of sugar in the urine is usually small.

Prognosis.—In acute diabetes the *duration* varies from a few days to eight or ten weeks, while in chronic diabetes the course ranges from one or two to five or even ten years. When the disease commences in the declining period of life, the course is longer still. The severe forms are generally fatal, and occur, as a rule, at an early period of life and in persons with an hereditary taint. The mild types and those that occur later in life offer a more hopeful prognosis, and in certain cases the withdrawal of all carbohydrates from the diet will cause the sugar to disappear from the urine. Of the special varieties, *alimentary glycosuria* is altogether favorable in its course, *traumatic diabetes* somewhat less so, while the prognosis of the *pancreatic form* is quite unfavorable.

Stout persons bear saccharine diabetes better than lean. Diabetes in gouty subjects often pursues a favorable course. Pre-existing affections may render the prospect quite gloomy, and certain complications indicate grave danger (coma, phthisis, gangrene, pneumonia, cardiac weakness, nephritis). Of 108 such cases, 64 per cent. terminated fatally (Wegeli), and between the ages of four and five years 20 out of 29 cases perished. The appearance of β -oxybutyric and diacetic acids in the urine is of serious omen. Cases showing heredity give an increased mortality rate.

Diagnosis.—Diabetes is distinguishable by means of (1) its causal influences and its pathologic antecedents and relations; (2) its gradual onset, often marked by certain suspicious symptoms (*e. g.* debility, impotence, symmetrical sciatica, cataract, furunculosis); (3) the persistent (rarely intermittent) presence of glycosuria, polyuria, and, later, acetoneuria and albuminuria; (4) the inordinate thirst and appetite; (5) cutaneous boils, carbuncles, gangrene, pruritus vulvæ in the female, balanitis in the male; (6) neuritis (especially double sciatica), diabetic tabes, and coma; (7) muscular cramps; (8) special complications; and (9) the long course with slowly progressive asthenia and wasting.

In suspicious cases, even before the discovery of sugar in the urine, grape-sugar may be administered for diagnostic purposes. If glycosuria result, the cases are to be treated just as in pure diabetes. Transient glycosuria, however, is not the genuine affection. Grape-sugar must be eliminated for weeks, months, or years (von Noorden).

Blood-test.—Williamson's blood-test, depending upon the power of diabetic blood to change a warm alkaline solution of methylene-blue to a dingy yellow color, has decided value. It occurs constantly.

Treatment.—1. A properly regulated diet is of the first importance. Such food-articles as contain starch or sugar (honey, sugar, ordinary flour or bread, biscuits, rusks, toast, arrow-root, oatmeal, cracked wheat, potatoes, tapioca, sago, peas, beans, turnips, carrots, parsnips, asparagus, artichokes, squashes, beets, corn, rice, hominy, the stalks and white parts of cabbage, lettuce, broccoli, figs, grapes, prunes, apples, pears, bananas, jams, syrups, sweet pickles, chocolate, cocoa, liquors, and especially sweet wines) are either to be altogether prohibited or restricted to definite quantities, as will be pointed out below. Among articles to be forbidden are also the livers of animals, mollusks (oysters, etc.), and the inside meat of crabs and lobsters. The chief diet must be animal, since the non-nitrogenous substances are to a very limited extent, and in some instances not at all, assimilated. My own plan is to first note the effect of a rigid dietary as follows:

(a) *Animal food*: Fresh meats, poultry, game, bacon, ham, fish of all kinds, including crabs and lobsters (except the inside meat of the latter). Fatty substances in large quantities (3vij—256.0—daily), with a view to restricting nitrogenous destruction, are highly commended by Klemperer. The free use of butter is urged, while eggs, cream-cheese, curds, and buttermilk are also allowed.

(b) *Vegetables*: Sour-kraut, lettuce, sorrel, mushrooms, water-cresses, spinach, chicory, celery, cucumbers, mustard-cress, and pickles of various sorts (except sweet). Soya bean, in which the starch and fermentable carbohydrates are removed, or *sarton*, which contains 35 per cent. of vegetable protein, is recommended by Von Noorden and Lampe.

(c) *Bread*: The crust of a French roll, first recommended by Flint. Ebstein has recently very highly recommended aleuronat bread; it contains a large proportion of vegetable albumins. The so-called No. 1 gluten biscuit¹ is the only form of gluten bread made in this country that does not contain nearly as much starch as the white flours (Tyson). Mosse and Sawyer² find that potatoes, steamed with their skins on to retain the potash salts, are often well borne in diabetic glycosuria. They advise the substitution of potato flour for wheat in bread, cake, etc.

(d) *Fruits*: Lemons, oranges, and nuts (except chestnuts).

(e) *Beverages*: Milk enough for cooking purposes; tea and coffee, sweetened with glycerin or saccharin; alkaline mineral waters (Saratoga-Vichy, Seltzer-water), simple water with some brandy, and acidulated drinks; Bass's ale, in which all the sugar is converted into carbonic acid and alcohol, and certain acid wines (claret, Rhine).

This strict diet usually causes the sugar to diminish greatly in amount, and in many cases to disappear entirely. If the patient keeps well-nourished and strong, carbohydrates should not be added, since there is no toleration for the latter. On the other hand, Pilosohof³ found that a small amount of carbohydrate (two apples) added to the albumino-fatty diet caused a diminution of sugar and acetone. An exclusive oatmeal diet for a few days, to be alternated with a diet consisting of flesh,

¹ This is made by the Battle Creek Sanitarium Co., of Battle Creek, Mich.

² *Brit. Med. Jour.*, March 5, 1904.

³ *Roussky Vrach*, November 25, 1906.

greens, butter, cheese, and the like has been advocated. Pari and others believe that the starch of the oatmeal has a specific action in this disease. The glycosuria and polyuria must not be relieved at the expense of the general strength of the patient. Von Noorden claims that a non-carbohydrate diet improves tissue-metabolism, thus increasing the system's power of warehousing carbohydrates, and recommends a rigid albuminoid diet at intervals of a few months. S. Solis Cohen recommends levulose as a form of sugar that can be assimilated without augmenting the excretion of glucose. With lean patients he uses 3j (32.0) per day; with stout persons, only enough to act as a sweetening agent. Lactose has been found to give similar results. As a substitute for the latter agents a small amount of ordinary bread (which contains 55 per cent. of starch) or potatoes may be allowed. The effects upon the general condition of the patient (body-weight), as well as upon the glycosuria (ascertained by a daily quantitative estimation of the sugar in the urine), are to be carefully noted, and the proportion of carbohydrates may be increased gradually until the limit of the system's ability to assimilate them is found. A more generous dietary is allowable only after the sugar has been absent from the urine for a couple of months, and then it is to be adopted in a gradual manner. A skimmed-milk diet has been recommended by Donkin, Tyson, and others.

2. Next to an appropriate diet stand certain directions as to **proper hygienic living**: (*a*) All forms of mental excitement and worry must be avoided; (*b*) moderate and regular physical exercise aids metabolism, and is thus directly useful; massage may be substituted for active exercise when the latter is prohibited on account of weakness; (*c*) the diabetic requires a temperate and equable climate; (*d*) a daily tepid bath if the patient be feeble, and a cold bath if he be strong, are to be commended; (*e*) flannels should be worn next to the skin all the year round; (*f*) the living and sleeping apartments must be thoroughly ventilated; Vaughan recommends sleeping in the open air in elderly subjects; (*g*) the teeth must receive careful attention in order to prevent caries.

3. The **medicinal measures** play a subsidiary part in diabetic therapeutics and opium is our best antiglycosuric drug. It is not necessary to employ it in all cases, but it may be tried if the dietetic and hygienic treatment fails to effect a cure. Opium seems not only to exert an influence over the polyuria and the excretion of sugar, but it almost invariably lessens the intense thirst and conduces to refreshing sleep. The drug is well tolerated by diabetics. The commencing dose may be gr. j (0.0648) three times daily, and later increased to gr. v (0.324) or even to gr. x (0.648) three times daily. If morphin be employed, we may begin with gr. $\frac{1}{4}$ (0.0162) and increase the dose to gr. j (0.0648) or more three times daily. Pavy warmly advocates the use of codein (gr. $\frac{1}{2}$ — $\frac{1}{2}$ —0.0324—0.1944, three times a day). My own best results have been obtained from the use of the latter remedy in the form of the sulphate, in ascending doses, commencing with gr. $\frac{1}{4}$ (0.0162), three times a day, and augmenting the dose by gr. $\frac{1}{4}$ (0.0162) every second day until gr. ij—0.129 (rarely more) are taken thrice daily. Codein possesses the advantage of being less constipating and less likely to disturb the digestive function than either opium or morphin. In patients of a full habit the alkaline waters exercise a valuable influence—Bethesda,

Carlsbad, and Vichy of France have long had a reputation. For the foreign water our native alkaline waters may be substituted, especially the Saratoga-Vichy. While these are valuable adjuncts, they are without the curative effect that is claimed for them by certain authorities.

Among other therapeutic agents that have been employed are the following: the solution of the bromid of arsenic, $\mathfrak{Mij-v}$ (0.199–0.333), three times a day, after meals—in some cases a useful adjuvant to the treatment above outlined; potassium bromid, gr. xx (1.296), three times a day, approximating in efficacy the latter remedy; guaiacol, $\mathfrak{Mv-x}$ (0.333–0.666), three times a day in a tablespoonful of milk or cod-liver oil, has given excellent results (Clements); antipyrin (gr. x—0.648), three times a day; sodium salicylate, gr. xv (0.972), and aspirin, gr. v (0.324), three times daily, lessen the formation of sugar; and strychnin, gr. $\frac{1}{30}$ (0.0021), three times daily, is an almost invariably useful remedy. Rudisch¹ observed that methylbromid of atropin in increasing dosage renders diabetics tolerant of larger quantities of carbohydrates. Of the numerous remedies in whose favor convincing evidence is wanting, but which are employed by different clinicians, the following may merely be enumerated: Fowler's solution, potassium iodid, iodoform, lactic acid, nitroglycerin, creasote, quinin, jambul, lithium, and methylene-blue.

The treatment of diabetes by *fresh pancreas* or by dry or glycerin extracts has been generally unsuccessful. Fitz, however, mentions a case in which remarkable improvement followed the exhibition of raw calf-pancreas. These preparations have been employed to supply the ferment (internal secretion) essential to the assimilation of sugar. R. Lépine has obtained from the fresh pancreas, from saliva, and from the diastase of malt a glycolitic ferment by a method which, he tells us, still requires to be perfected. This agent he has used in 4 cases of diabetes with a fair degree of success. Williams tried grafting sheep's pancreas in diabetics in two cases, but the results were unsatisfactory. Gilbert and Carnot found that *extract of liver*, administered by rectal injection, caused a marked decrease in the excretion of sugar.

Thyroid extract, in small doses, was followed by immediate improvement in two of my cases; it is indicated in alimentary glycosuria.

4. Symptomatic Treatment.—Most symptoms demanding therapeutic interference the competent physician is prepared to meet by following general rules. The management of diabetic coma, however, will be briefly discussed. Klemperer urges the use of fatty substances in large quantities as the best means of restricting nitrogenous destruction, and thus preventing the condition to which diabetics so frequently succumb. When a disgust develops for fats a substitution-method of treatment consists in administering alcohol (\mathfrak{Ziss} —48.0—per day). Alcohol in *small* quantity checks waste (Hirschfeld). When indications of coma arise, carbohydrates should also be added to the diet.

The coma is almost certainly due to intoxication with beta-oxybutyric acid, and treatment with alkalis has given the best results. When an attack threatens, sodium bicarbonate should be given in large doses (\mathfrak{Zij} —96.0 daily) until the urine becomes alkaline. In the attack, the intravenous injection of the same remedy has proved of undoubted value

¹ *Medical Record*, 1909, xxvi, 1093.

and is to be used freely. Normal salt solution by hypodermoclysis may be tried. Oxygen should be inhaled, and strychnin, digitalis, or ether may be given hypodermically. Prolonged tepid baths with occasional douching have seemed to produce beneficial results, and are worthy of a trial. Elimination from the bowels is to be increased. The *x*-rays projected over the hepatic region have caused decrease in glycosuria.

DIABETES INSIPIDUS.

Definition.—A chronic nervous affection, characterized by constant thirst and an excessive flow of urine, which, however, is free from sugar and albumin and is of low specific gravity.

Pathology.—No definite or characteristic lesions have been noted, though some degree of enlargement of the kidneys, together with sacculation, due to pressure backward upon the renal structure by the enormous quantities of urine in the bladder and ureters, has been observed. The ureters and pelves of the kidneys may be dilated, and the bladder, owing to constant over-distention, may be hypertrophied. The nervous lesions are diversified, but are not peculiar to simple polyuria. Most important, perhaps, are the tuberculous and other tumors about the floor of the fourth ventricle.

Etiology.—(a) Diabetes insipidus is often induced by *nervous influences*—shock, fright, etc.—and may also be of traumatic origin. In the majority of the latter cases it follows injuries to the head, but also, more rarely, it may be traced back to injuries of other parts of the body. Tuberculous and other lesions in the vicinity of the floor of the fourth ventricle may produce polyuria. It has also been caused by paralysis of the sixth nerve, with or without meningitis. (b) It may occur during convalescence from *acute infectious diseases*. I have seen 2 instances after influenza in young subjects. (c) *Intemperance*, especially the consumption of inordinate quantities of malt liquors, proves a cause. In several of my own cases the amount of urine passed was out of all proportion to the quantity of fluid ingested. (d) *Heredity*.—Weil found in four generations of a certain family consisting of 91 members, that 23 exhibited continuous polyuria—all, however, remaining in good health. (e) *Age*.—The disease is relatively more frequent in childhood and early adolescence than is diabetes mellitus. Of 70 cases collected, 22 were under ten years of age, and 13 between ten and twenty (Roberts). Diabetes insipidus may be *congenital*. (f) Most cases occur in males as compared with females. (g) Diabetes insipidus may be, though rarely, a sequel of diabetes mellitus occasioned by traumatism to the head.

Nature of the Affection.—The specific cause of the disease, if it have one, is as yet undiscovered. We are totally ignorant of its true nature, though the facts discovered by Bernard, that either a puncture at a certain spot in the floor of the fourth ventricle or section of the vagus causes polyuria, go to show that it is of nervous origin. It is true that the disease may come on in persons apparently in robust health without discernible causative agencies. In many instances, such as organic affections of the brain or abdominal tumors, the condition is purely symptomatic, and these are probably not to be classed as cases of gen-

urine diabetes insipidus, which is a vaso-motor neurosis, usually of central, though sometimes of reflex, origin.

Clinical Symptoms.—The onset is *gradual*, as a rule, but when it follows a fright or traumatism it may develop quickly. There are two main symptoms—the passage of an enormous quantity of limpid urine, and the constant thirst. The daily *amount* of urine varies from 20 to 60 pints (10–30 liters); it is transparent, and the specific gravity is low (1001 to 1005). While the percentage of solids is lessened, the total is usually about normal, and may even be increased. *Albumin* and *sugar* are rare, but in a few cases inosite has been detected. The act of micturition is of very frequent occurrence, and the quantity of urine passed at each sitting surprisingly large. The persistent *thirst* necessitates frequent drinking, but the voracious appetite seen in diabetes mellitus does not mark this disease, in which the appetite is only slightly increased. As a result of the polyuria the skin and mucous membranes are abnormally dry, as in genuine diabetes. But, unlike the latter affection, a fair degree of bodily nutrition is maintained as a rule. The saliva and other digestive secretions are scanty, and this, together with the good appetite, is a fact which explains the disturbances of digestion sometimes met with. The tolerance of the system to alcohol is often phenomenal. Associated nervous phenomena are frequently observed, such as neurasthenic symptoms, insomnia, and chorea.

Prognosis.—The majority of instances proceed to recovery sooner or later, while others pursue an almost endless course—forty or even fifty years in duration—and the patient meanwhile retains his general good health. There is a small group of grave cases that are due to organic diseases either of the brain or abdominal organs (tuberculosis). Death may also be occasioned by some intercurrent affection.

Diagnosis.—The clinical recognition of diabetes insipidus rests upon—(a) the enormous amount of urine passed; (b) its low specific gravity; and (c) the absence of sugar and albumin.

Differential Diagnosis.—Among affections that must be differentiated are *diabetes mellitus*, which has a single point of resemblance—namely, the polyuria; *hysteric polyuria*, which is transient and accompanied by other hysterical manifestations; and *chronic interstitial nephritis*, which generally distinguishes itself by the presence of albumin and hyaline casts in the urine, arterio-sclerosis, and cardiac hypertrophy.

Treatment.—The amount of drinking-water is to be moderated in a gradual, cautious manner, and the patient should be warned not to exceed his actual necessities. I find also that methodic physical exercise and other hygienic means act beneficially. Galvanism has its advocates; it is most useful when cord lesions exist.

Of medicines, nervines, especially valerian and its preparations, are useful in the idiopathic variety of the complaint, and may be given in the form of the ammoniated elixir (3j–ij—4.0–8.0) three or four times daily. The valerianate of zinc, quinin, and iron may be variously combined, according to the indications presented by special cases. Ergot and gallic acid have long enjoyed a high reputation in this disease. The commencing doses should be moderate, and then be increased until full physiological doses are employed, this method often bringing about ad-

mirable results. Antipyrin, acetanilid, the bromids, and arsenic have been extensively employed and lauded by different writers in the treatment of this affection. My own best results have been attained by the use of ergot. The potassium iodide is much vaunted. Next to this agent the bromids and acetanilid, given alternately at intervals of a couple of weeks, have been found to be most useful. If a primary disease, *e. g.*, syphilis, exists, it must be met on intelligent general therapeutic principles.

ARTHRITIS DEFORMANS.

(*Rheumatoid Arthritis; Rheumatic Gout.*)

Definition.—A chronic disease, characterized by progressive changes in the arthritic structures (cartilages, synovial membranes, etc.) and by osseous periarticular formations, producing great deformity. The affection may rarely be acute in its course.

Pathology.—Among early gross changes there may be an effusion into the affected joints, but this disappears later. The cartilages are absorbed, the process beginning centrally, where there are both the maximum amount of friction between the opposed cartilaginous surfaces and the minimum blood-supply. Disappearance of the cartilages is naturally followed by contact of the ends of the bones, the latter becoming polished and resembling ivory as the result (eburnated). The friction between the bony extremities may lead to absorption of the latter.

At the periphery, where pressure is slight or even absent, the cartilages become greatly thickened in consequence of persistent irritation, and later become ossified, forming osteophytes which overlies the articular surfaces. These may lock the joints. Bony nodules may also be formed from the periosteum of the bony shafts.

Almost simultaneously the *synovial membranes* become inflamed, a proliferation of their cells taking place, and this exudate may undergo organization and rarely ossification. Later the *capsule* and the *ligaments* are thickened, causing a restriction of movement of the affected joints and producing pseudo-ankylosis. Less frequently they soften and weaken to such an extent that often partial, and sometimes complete, dislocation of the joints ensues; but displacement of the ends of the bones, amounting even to complete luxation, may also be due to absorption. This is often observed in the head of the femur, producing the so-called *morbus coxæ senilis*. Muscular wasting occurs and may be profound. Neuritis has been noted.

The *histo-pathologic* changes consist in cell-proliferation, with fibrillation and softening of the matrix of the cartilages, followed by absorption due to pressure. At the margin, however, proliferation of the cells leads to massive nodulation.

Etiology.—The *nature* of the disease is still dubious, though the old view, that it is *closely* connected with rheumatism on the one hand or gout on the other, should be abandoned. J. K. Mitchell long since maintained that rheumatoid arthritis is of neurotrophic *origin*, being espe-

cially dependent upon affections of the spinal cord, and without stopping to adduce all of the facts that tend to support this theory, the following deserve mention: (1) Diseases of the cord (locomotor ataxia, etc.) are known to cause arthritic conditions; (2) The character of certain causal factors, such as nervous shocks, griefs, etc.; (3) The symmetry of the joint-deformities; (4) The time of occurrence; and (5) Noticeable trophic disturbances that are frequently associated. Falli¹ autopsied 4 cases, 2 of which were typical, and in the latter lesions were found in the anterior horns of the spinal cord, atrophic in the first case, but degenerative as well as atrophic in the second. According to Falli, not all cases of arthritis deformans are to be interpreted as instances of nervous disease. The *microbic* theory of the disease claims a small but increasing number of supporters.

Bacteriology.—Dor claims to have succeeded in finding a definite organism. He also claims to have reproduced the disease by injecting cultures directly into the blood of rabbits, and considers the germ an "attenuated culture" of the *staphylococcus pyogenes aureus*. v. Dungere and Schneider isolated after death from the mucus of the gall-bladder, and also from the exudate in the joints, small diplococci that did not resemble the organisms previously described by Blaxall and Schüller. Injections of the cultures into the knee-joint of rabbits resulted in the production of lesions similar to those observed in the patient.

Predisposing Causes.—(a) *Nervous shocks*, mental worry, and deep grief. (b) *Females* are more frequently victims than are males, the proportion, according to the statistics of Garrod, being about one to five in favor of the former sex. To account in part for its greater frequency in women is the fact that sterility and certain ovarian and uterine complaints seem to exert a strong etiologic influence. (c) *Age* exerts a decided influence. It is most frequently contracted in the third decade of life, though it has been noted as late as the end of the fifth. It occurs also in children, though rarely. Out of 307 cases treated in the Devonshire Hospital during 1892, only 2 per cent. manifested the disease before the age of ten. (d) *Heredity* has been traced in some instances, and in many a *family tendency* to joint-affection. (e) Though it occurs in all classes of society, the *poor* or those exposed especially to debilitating influences are more liable than the *rich*. (f) *Infectious diseases* may have an influence. (g) Ewart² recognizes some mixed conditions in which rheumatoid arthritis may supervene on the gouty diathesis.

(1) **Symptoms of the Chronic Form.**—At first one joint, usually of the hand, is slowly involved; soon the corresponding joint on the opposite side is attacked. These may recover apparently, but are soon reinvaded and grow progressively worse. The affected joints slowly enlarge, and are moderately painful, particularly on movement. *Pain*, however, may either be slight or even absent, or severe, if the synovial membrane be involved. There is neither redness nor tenderness, as a rule, but on palpation an effusion, variable in extent, is generally detectable. The *course* during the early stage is often marked by periods of improvement, alternating with exacerbations in the local symptoms, and

FIG. 32.—Hand of M. R., aged fifty years, showing characteristic deformity, including outward deflection of fingers, in advanced arthritis deformans.

especially in the swelling and pain. While, as intimated, one or two joints only are affected at the start, gradually those of the feet, arms, legs, and trunk are invaded symmetrically, until, in the worst cases, every joint is deformed.

The most characteristic symptom is the *deformity*, which manifests itself earliest in the hands. The fingers are generally pointed toward the ulna, rarely toward the radius, and the presence of the osteophytes and the immensely thickened capsular ligaments, together with the retracted muscles, all tend to alter entirely the shape of the joints. The fingers, for example, are flexed and extended upon the hand, and sometimes overlies one another. With the progress of the deformity a partial, and less often a complete, luxation of the joints occurs (see Fig. 32). The joints may become finally either quite fixed, owing to the presence of the periarticular osteophytes, or a limited degree of movement may remain.

Palpation and auscultation of the involved joints reveal crepitation during movement. Strangely enough, the thumb remains intact, compensating for the loss of the functional movement of the fingers to a remarkable extent. In addition, the hand is sometimes less affected than the rest of the joints—a fact which enables the patient to perform a great variety of delicate movements, or even to engage in useful and surprisingly skilful handicraft. The adjacent muscles become wasted and are the seat of contractures, causing flexion of the limbs, especially of the thigh upon the abdomen and the leg upon the thigh. Other trophic changes, such as paresthesia and pigmentation or glossy areas of the skin, may be observed. In 3 of my cases onychia was present. In extreme instances the decubitus is lateral and the patient utterly helpless.

The *course* of the disease throughout the more advanced stages is exceedingly variable. Its advance may be arrested and the general health remain unimpaired, and this may take place after implication of but a few joints, so that the entire affection may be confined to a comparatively small part of the body, either in the upper or lower extremities. In progressive cases more or less gastro-intestinal disorder arises; the symptoms of indigestion appear, the appetite is impaired, and anemia develops. The patient's sufferings make him irritable. Hypochondriasis may be a concomitant. In established cases the pulse is persistently rapid and the skin inclined to free perspiration.

Clinical Varieties.—(1) Of the **chronic form** there are certain subvarieties. The disease may be limited to a single joint (*monarticular*), this form most commonly affecting the hip-joint, when it is known as *morbis coxæ senilis*. It is seen generally in old men, and often follows an injury. Its features—pathologic and clinical—including the muscular wasting, are the same in kind as those of the *polyarticular* variety. Monarticular arthritis deformans may also be confined to the shoulder-joint or the knee, and, as in the preceding form, men who have passed the middle period of life are mainly affected.

A special variety, which is generally not monarticular, involves only the vertebræ (*spondylitis deformans*). With this may be combined disease of one or more of the neighboring large joints, forming the *spondylose rhizomélisque* of Marie, or the condition may be confined to the cervical spine, as in a recent case of my own, thus preventing flexion of the head.

A fair degree of rotation usually remains, but it sometimes happens that the entire spinal column is involved and held in a perfectly rigid position.

Still another form in which the distal joints of the fingers become knobbed (*Heberden's nodes*) demands separate description. Heberden's nodosities occur chiefly in women between the thirtieth and fortieth years, though I have seen one case which began after the fiftieth year. According to Heberden, who first described them, the nodes have no intimate association with gout, and this view coincides with my observations. At first the affected joints become *swollen, tender, slightly red, and painful*, and then seemingly undergo great improvement. The condition however, is progressive, advancement occurring in the form of fresh exacerbations, which are only rarely traceable to errors in diet, and are separated by periods of remission. The morbid process is the same as in rheumatoid arthritis, and the destructive changes in the joints proceed until distinct hard nodules are formed. These are usually most marked at the sides of the extensor surfaces of the second phalanges. The disease does not spread to any of the larger joints, and, although incurable, it is free from danger to life.

(2) **The Acute Form.**—This is comparatively rare, and occurs commonly between the ages of twenty and thirty. It occurs in children, and is more common in women than in men. Among its common antecedents in women are pregnancy, delivery, excessive lactation, and the menopause. *Multiple arthritis*, affecting both the large and small joints, sets in acutely, and there are pain and either a slight redness or a considerable swelling, due chiefly to an effusion which is intra- rather than periarticular. There are only a slight tendency to migration from joint to joint, and a slight febrile disturbance.

Still described a form of chronic joint-disease in children which he thinks presents differences sufficiently marked to suggest a distinct clinical and pathologic entity, and differing from the rheumatoid arthritis of adults. It is defined as a progressive enlargement of the joints associated with general enlargement of the glands and enlargement of the spleen. He has studied 22 cases, 19 of which came under his personal observation. It occurs before the second dentition. Stiffness, general thickening of the tissues around the joints without redness or tenderness, except in very acute cases, with limitation of movement and more or less rigid flexion of the joints, characterize the arthritic disturbance. The most distinct feature of the disease is the enlargement of the lymphatic glands, those in relation to the involved joint being primarily affected. The glandular swelling is general and constant, and with the enlargement of the spleen, points toward an infectious origin. Cardiac complications are absent. The *course* of the disease is slow.

Differential Diagnosis.—The diagnosis between the chronic form of the disease and *chronic rheumatism* is often extremely difficult. In the latter, however, a few of the larger joints only are involved, while there is an absence of the peculiar deformity and marked fixity of the articulations. On the other hand, cardiac complications are absent in chronic rheumatoid arthritis, and the course is progressive. A *mono-articular arthritis* which differs in its morbid process from rheumatoid arthritis sometimes affects the shoulder-joint. It is not uncommon, and is "characterized by pain, thickening of the capsule and of the ligaments, wasting of the shoulder-girdle muscles, and sometimes by neuritis"

(Osler). I have met with 5 instances of this sort, in all of which pain was intense and the course subacute. All ended in recovery.

The frequency of the occurrence of intercurrent acute polyarthritis in arthritis deformans causes the danger of mistaking this for acute rheumatism.¹ Acute rheumatoid arthritis is to be discriminated by the special etiologic factors, the less severe pain, the less marked redness, the slight tendency to migration from joint to joint, the slighter febrile disturbance, and by the practical freedom from cardiac complications. *Gout* will be distinguished in the description of that disease.

Prognosis.—Though incurable, rheumatoid arthritis is not immediately dangerous to life; in some cases improvement, and in a smaller proportion arrested progress of the disease, may be expected.

Treatment.—This especially involves measures that are directed toward the improvement of bodily nutrition—a generous dietary, systematic warm bathing, and an abundance of fresh air, with properly regulated physical exercise. Tonics may be necessary to invigorate the economy, and iron to overcome the anemia. The prolonged use of cod-liver oil has given me excellent results. Of special agents, the most satisfactory in their effects if administered early are iodine and arsenic. An eligible form of the latter is arsenious acid, given in granules (gr. $\frac{1}{36}$ —0.0018, after food); the former may be administered in the form of a saturated solution of sodium iodide, of which 10 to 15 drops may be given in milk one hour after food. Sheffer advocates sodium silicate well diluted (dose 1.5 to 3 grams daily). The silicates are useful in overcoming defective metabolism. The use of extract of thyroid is favored in certain cases because of the possibility that aberrant function of the ductless glands may be concerned in the etiology of the disease. The patient may be sent to a warm climate in winter and to a cooler one, preferably a mountain-resort, in summer. These patients also do well at certain mineral springs, such as the sulphur springs of Virginia, the hot springs of Arkansas or Töplitz, at Baden in Switzerland, and the warm sodium chlorid baths in Wiesbaden. Hot mineral spas should only be resorted to in the early period of the affection. Strümpell has seen excellent results follow the employment of hot sand-baths, which can be used at home. Stewart advocates the Tallerman method of treatment—*i. e.*, of superheated dry air. Short employs the same apparatus with a view to producing diaphoresis. Immobile contractures may be broken up under anesthesia and tendons lengthened by tendoplasty, followed by plaster-of-Paris dressing until pain and irritation have subsided (Ochsner). Murrell² has used a serum, which has acted admirably.

Eliminative Treatment.—Guaiacol carbonate may be given in doses of from 5 to 15 grains (0.3–1.0 gm.) daily and increased. This combines with the toxins, and is eliminated as guaiacol sulphate (Bannatyne).

The *local means* are of value. If the joints be inflamed, cold compresses, covered with oiled silk, to which some narcotic agent may be added, will afford relief. This should be followed by thorough and systematic massage, which is our best measure for the reduction of the swelling (by promoting absorption) and for lessening joint-rigidity, and restoring the atrophied muscles. Swedish movements are useful in maintaining mobility and mechanical or electric vibration may prove helpful.

GOUT.

(Podagra.)

Definition.—A form of perverted nutrition due to an auto-infection, accompanied by the formation of a variable (usually increased) amount of uric acid, and characterized clinically by attacks of acute arthritis, with or without uratic deposits in and around the joints.

Nature of the Affection.—The numerous theories that prevail at present in regard to the disease are irreconcilable, but it seems certain that there is (a) an excessive absorption of nutritive substances, both solid and liquid; (b) a disordered metabolism growing out of the effects of imperfect physical development, combined with too little muscular exercise; (c) a defective elimination of waste-products, although in some cases a normal elimination of waste-products exists.

There are a number of *uric-acid theories*, some of which may be briefly mentioned: 1. Garrod contends that an acute attack of gout is invariably produced by an excess of uric acid in the blood, due to increased formation and greatly decreased elimination; also, that inflammation is caused by the deposition in the joints of sodium urate. 2. Haig holds that there is a diminished alkalinity of the blood, and that the latter cannot therefore hold the uric acid in solution, and not an excessive production of uric acid. 3. Ebstein thinks it probable that there exist an excessive production and accumulation in the blood of uric acid. The surcharged blood excites local inflammation, followed by necrosis, and uric acid deposits. 4. Sir William Roberts believes that acute attacks of gout are dependent upon the precipitation of the crystalline biurate of sodium; that the urate is transformed into the less soluble biurate in the blood. 5. V. Noorden concludes that the essential process is a tissue-necrosis attributable to the presence of a hypothetic ferment, and that the uric acid, which is without etiologic effect, is deposited at the necrotic focus. Hall¹ affirms that as an etiologic entity, uric acid must be definitely discarded. 6. Klemperer² has shown as the result of observations made in cases of gout, that as long as the function of the kidneys is not materially interfered with the presence of considerable amounts of uric acid in the blood must be attributed to increased formation. But the presence of an equivalent of uric acid in the blood in certain affections other than gout (*e. g.*, leukemia) shows that this factor is not the sole cause of gout. 7. Morhorst states that in any alkaline liquid the basic substances combine with uric acid, if this be present, to form a urate. These uratic precipitations are met in non-vascular tissues only, the alkalinity of which is less than that of the blood, and that they are the essential cause of the symptoms. 8. Kolisch maintains that when the kidneys are healthy the alloxuric bodies are, in great part, excreted as uric acid; but when they are diseased the xanthin bases are increased at the expense of the uric acid. Chittenden and others, however, hold that the xanthin bases are practically free from toxic effects. 9. Luff thinks that uric acid is formed in the *kidneys* from a combination of urea and glycocin, an increased amount of the latter substance being formed in the liver. 10.

¹ *The Practitioner*, 1906, lxxvi., p. 361.

² *Deutsche medicinische Wochenschrift*, 1895, No. 40, p. 653.

Duckworth insists that gout is essentially of nervous origin. The view that failure of the renal function precedes the development of gouty manifestations, and the older view, that an increased proportion of uric acid is found in the blood, are widely accepted.

Pathology.—The post-mortem history of gout is concerned principally with the arthritic changes, including the deposits of the urate of sodium in the cartilages, the ligaments, and the synovial membranes. These are fluid in their earliest state and contain numerous small crystalline masses; they soon inspissate and later become hard and dry (tophi). The latter excite secondary inflammatory changes that may lead to fibrous overgrowths, distortion, and fixation of the joints. Gouty tophi may be absorbed or they may finally be discharged through the skin in consequence of an ulcerative process. The chalky concretions have been found also in the cartilages of the ears, less frequently of the nose, eyelids, and larynx. They have also been described in the periosteum and along the tendons of the palms of the hands, where they produce a characteristic form of contraction of one or more fingers (Dupuytren's contraction). Charcot has found them in the penis. If death occur in the *acute* attack, hyperemia and swelling of the capsule, ligaments, and synovial membrane are found, together with an inflammatory exudation into the joint.

The *kidneys* are usually involved, the changes being similar in character to those observed in the joints, and innumerable areas of necrosis, followed by uratic deposits, are seen throughout the organs, though chiefly in the papillæ. Osler says that "the presence of these uratic concretions at the apices of the pyramids is not a positive indication of gout." N. S. Davis, Jr., points out that the kidneys are affected in spots, with intermissions in the degenerative changes, which are microscopical in size, until finally large areas are involved. Granular contracted kidney (chronic interstitial nephritis), with or without arteriosclerosis, is sometimes caused by the gouty condition (*vide* Interstitial Nephritis).

The *heart and blood-vessels* always present changes. Gout induces arterio-sclerosis, and the latter in turn causes cardiac hypertrophy, particularly of the left ventricle. In chronic cases fatty degeneration of the heart-muscle sometimes occurs, and chronic valvulitis, with deposits of urate of sodium in the valves, has been noted. Chronic bronchitis, asthma, and emphysema are among the more common changes connected with the *respiratory tract*, acute conditions being rare.

Etiology.—The following are the principal contributing causes:

(a) *Heredity.*—Garrod's dictum, "that more than one-half of all gouty subjects can distinctly trace their ailment to an hereditary taint," is doubtless correct, heredity from the grandparents, which is of not infrequent occurrence, being included in this estimate. If the better class of society alone be considered, the percentage will probably be still larger. It must not be forgotten, however, that patients out of pride represent other articular affections as gout. (b) *Age.*—Primary attacks are most frequent in middle life. They are rare before puberty, though exceptionally seen even in suckling infants; but after the age of puberty they become more frequent. After the fiftieth year they decrease rapidly in frequency, and are very rare in quite advanced life. The cases that develop quite early in life often show a striking heredi-

tary taint. (c) *Sex*.—The arthritic form is less frequent in women than in men, while the former are disposed to the irregular type of chronic gout quite as strongly as the latter. (d) *Diet*.—Over-indulgence in the pleasures of the table, together with defective muscular exercise, constitutes a potent factor, and this even in persons who are endowed with exceptional powers of digestion. (e) *Alcohol*, and particularly the fermented liquors, are among the chief favoring influences. The fact explains the relatively greater frequency of gout in certain countries (*e. g.* England and Germany), in which the heavier beers and ales are freely used, than in America, where lighter fermented drinks are more popular. The cases, however, are on the increase in this country. (f) *Social State*.—Most cases occur among the upper class of society, but there is also a well-defined form of “poor-man’s gout” due to an excessive use of malt beverages. (g) *Lead*.—Workers in lead furnish numerous typical examples of gout. Garrod found that in 30 per cent. of the hospital cases the patients had been painters or workers in lead. He also showed that the administration of lead salts to gouty persons almost invariably determined a gouty paroxysm. Whether lead produces gout by arresting the excretory processes, and by thus inducing a fibroid change in the kidney and liver, as is held by Oliver of New Castle, is not definitely settled. Poore points out that gout produced by lead or chronic kidney trouble is constantly associated with anemia and emaciation, and forms a distinct clinical entity. We may presume the existence of a primary renal gout. (h) Cornillon and others detail cases in which injuries were followed by the first appearance of the disease.

Clinical History.—1. **Acute Gout.**—The earliest manifestations of the disease are apt to take the form of a more or less typical attack of *acute arthritic gout*. The latter is usually preceded by certain *prodromal symptoms*, which vary in different cases, but are almost constantly similar for the paroxysms of individual cases. The patient may complain either of slight muscular cramps and articular pains, or of dyspeptic disorder, or of an asthmatic seizure; or he may exhibit mental disturbance—irritability of disposition, broken, restless sleep, and depression of spirits. In a small percentage of instances, just prior to the attack the patient feels better than ordinarily. It has been observed that immediately before and also during the early part of a paroxysm the daily amount of uric and phosphoric acids found in the urine is diminished; but Klemperer has shown that no relation exists between the amount of uric acid present in the urine and the character of the disease.

The attack generally develops in the very early morning hours. The patient awakens suffering from pains in the metatarso-phalangeal joint of the great toe, that soon become excruciating, while the joint feels as if it were tightly compressed in a vise. The *local signs* of inflammation—heat, redness, swelling, and excessive sensitiveness—quickly supervene. The skin pits on pressure and becomes shiny. The *body-temperature* rises to 102° or 103° F. (39.4° C.), and the patient manifests intense irritability.

At the end of an hour or two the sufferings abate, the fever often declines, with free perspiration, and the patient may be able to pursue his avocation. During the next day some degree of enlargement and inflammatory edema remains, and on the following night the symptoms are usually repeated in all their violence. The condition usually pro-

gresses in this manner from four to seven or eight days, though after a few days the intensity of the paroxysms is apt to lessen. After the attack the swelling subsides and there is a slight desquamation of the skin, which resumes its normal color, and the general health is often unusually good. These so-called fits of gout usually recur from time to time, the duration of the intervals depending largely upon the patient's habits or routine of life. On the whole, the first interval is apt to be the longest, while later the intermissions may not exceed two or three months. With subsequent attacks the affection is apt to spread to other articulations. There is no tendency to suppuration.

2. Retrocedent Gout.—This term implies the sudden transmission of the arthritic process to some internal organ. During a paroxysm the joint-inflammation may quickly disappear with an equally sudden development of intense pain in the region of the stomach, vomiting, diarrhea, faintness, and a rapid, feeble pulse. Suppressive gout may attack the heart and produce precordial pain, dyspnea, cardiac palpitation, and much anxiety of mind. It may also excite pericarditis with a fatal result. Transmission to the head, with the development of intense cerebral symptoms (maniacal excitement, coma, and apoplexy), also occurs. Nervous phenomena, however, are more commonly due to uremic poison.

3. Symptoms of Chronic Gout.—Chronic gout follows the acute variety. The transition is gradual, the intervals between attacks shorter, while the attacks themselves grow milder and longer. At last the local inflammation does not appear. The condition extends to other joints: first, to the corresponding joint on the opposite side, then to the other toes and the ankles. Later, the fingers and wrists may be invaded, but almost never the largest joints (hip, shoulder). With the progress of the affection the chalk deposits slowly and gradually increase until the characteristic deformity is produced. The skin covering the tophi may ulcerate, exposing the chalk-stones, an unmistakable picture. When the fingers are affected we note a deflection at the second or third joint, constituting a peculiar habitus.

Among important *associated conditions* are chronic gastric catarrh, arterio-sclerosis, cardiac hypertrophy with considerable functional disturbance of the heart, and "contracted kidney," forming a much complicated yet easily recognized clinical picture. If in cases of this sort the *urine* of a gouty person is carefully examined, and is found to contain a small percentage of albumin and tube-casts, the whole train of events becomes easy of interpretation. The cases may be divided into two classes: (*a*) those in which the complexion is florid and the general health vigorous; (*b*) those with pale, sallow facies, emaciation, and enfeeblement. These groups are chiefly dependent upon the differences in the etiologic factors. Gouty subjects often manifest unusual mental vigor.

The *course* of chronic gout is liable to be interrupted by acute exacerbations with fever, during which dangerous complications may arise—*e. g.* uremia, pericarditis, pleurisy, pneumonia.

4. Irregular Gout.—Says Sir Dyce Duckworth: "Gout manifesting itself anywhere but in a joint is to be considered irregular or incomplete." Such cases are confined chiefly to persons of gouty heritage, though I feel confident that the diathesis may be also acquired. But though the etiologic factors that produce lithemia also in time produce

gout, these two conditions should be discriminated; for, while in both we usually note an excess of uric acid in the blood, in lithemia there are no tophi present, and hence no necrotic foci in the joints or elsewhere. Irregular gout, then, rarely occurs in persons who have had previous typical attacks, but should any of the conditions described below as being dependent upon the gouty diathesis be associated, or should they alternate, with acute gout, they may be properly ascribed to the latter. On the other hand, when these conditions occur in persons who are free from hereditary taint, and who are not addicted to the intemperate use of alcoholic beverages, or excessive indulgence in the pleasures of the table, and are not possessed of luxury- and rest-loving temperament, the diagnosis of irregular gout is to be made with extreme caution. It is perfectly justifiable to apply a therapeutic test when other means of diagnosis fail.

The features of irregular gout are exceedingly diversified; the following are the more important:

(a) *Joint- and Muscle-pains*.—The muscular pains may be anywhere, and “flying” in nature, but the muscles of the back of the neck, the lumbar region, the abductors of the thigh, and the gastrocnemii are especially liable (Tyson). These pains are most severe in the early morning hours and subside as the day grows. Articular pains attended with some degree of swelling and deformity of the joints (the latter, however, not due to uratic deposits) may be of gouty origin; and, according to Paget and Garrod, Heberden’s nodosities (previously described under Rheumatoid Arthritis) may present vesicular eminences due to gout.

(b) *Gastro-intestinal Disturbances*.—The symptoms referable to the intestines are identical with those presented by lithemia. In one of my cases intestinal colic followed by diarrhea put in an appearance at long intervals. Tonsillitis, pharyngitis, pericarditis, and even parotitis, may also be manifestations.

(c) *Cardio-vascular Symptoms*.—Just as in pure lithemia, so in atypical gout, the increased amount of uric acid usually present in the blood, by increasing the blood-tension, excites arterio-sclerosis and chronic interstitial nephritis—affections which are fully described in appropriate sections of this work.

(d) *Nervous Manifestations*.—The different varieties of headache, including migraine, are common. Sciatica and other forms of neuralgia, tingling, itching, burning sensations, and even pain in the palms of the hands and soles of the feet, are of frequent occurrence. Hot and itching eyeballs are, according to Hutchinson, among frequent manifestations; apoplexy may arise, secondary to atheroma induced by gout; and rarely meningitis (basilar) is among the gouty morbid states. The latter also include certain psychopathia—insomnia, irritability of temper, and melancholia. The possibility of gouty neuritis is to be remembered.

(e) *Urinary Symptoms*.—The urine is highly colored, of high specific gravity, often scanty, and the standing specimen deposits lithic acid. This is not peculiar to gout, however. In many cases uric acid is in excess only at intervals, giving rise to so-called uric-acid showers, while at other times it is diminished in quantity. Fletcher¹ reports an investigation of the excretion of uric acid and phosphoric acid in a number of gout cases, and concludes that there is a close parallel relationship be-

¹ *The Practitioner*, August, 1903, p. 181.

tween the two. He believes that both are products of nuclein disintegration. Gouty persons are liable to gravel: I agree with Tyson, however, in thinking that the two conditions more frequently alternate than coexist. Intermittent glycosuria is also common in gouty subjects, and may lead to true diabetes mellitus; this glycosuria may alternate with uric-acid showers. With these affections—intermittent glycosuria and gout—obesity is not uncommonly associated. Oxaluria has been noted. Grandmaison believes the association of albuminuria with gout to be a frequent one, and that the early albuminuria is often intermittent. Among grave *secondary affections* chronic interstitial nephritis, with its characteristic features (slight albuminuria and later casts), very commonly develops, sooner or later, and cystitis (with gouty hemorrhage into the bladder), urethritis, prostatitis, and orchitis, all may be dependent upon gout.

(f) *Pulmonary Disturbances*.—Chronic bronchitis, to which asthma and emphysema are frequently secondary, often owes its origin to podagra.

(g) *Cutaneous Eruptions*.—Eczema is frequently associated with the gouty diathesis, and I have often observed eczematous eruptions alternating with the symptoms of bronchitis or gastric catarrh.

(h) *Ocular Disorders*.—The chief eye-symptoms are conjunctivitis and keratitis (with tophi in the cornea and eyelids), iritis, hemorrhagic retinitis, and glaucoma. Gouty involvement of the ear (external canal and the auricle particularly) occurs oftenest late in life, though hereditary gout may rarely cause ear symptoms shortly after birth.

Differential Diagnosis.—The distinction between typical acute gout and *acute articular rheumatism* is a simple matter. But when, as is rarely the case, the former manifests itself as a polyarthritis, the discrimination is sometimes difficult. W. H. Thompson has pointed out that in gouty polyarthritis, when the knees, elbows, and phalangeal finger-joints are affected, the points of greatest tenderness on transverse pressure are over the condyles. On the other hand, in acute rheumatism the cutaneous tenderness is greater, while the points of maximum tenderness correspond with the tendons anterior and posterior to the joints. Moreover, gout distinguishes itself by its previous history (heredity, alcoholism, gluttony), by the tophi, which may be first detected in the ears or conjunctivæ, by the development of contracted kidneys, and the less marked fever. After repeated attacks deformities of the joints ensue. In a doubtful case the blood-serum may respond to Garrod's uric-acid test, as follows: Add 5 to 6 minims (0.399) of acetic acid to 2 drams (8.0) of blood-serum in a watch-glass; then place a linen thread in the solution and after twelve to twenty-four hours this will be incrustated with crystals of uric acid. The same result is obtained in leukemia and pneumonia,—affections from which gout is easily distinguishable.

Chronic rheumatism is distinguished from gout by the fact that the latter disease involves chiefly the small, and chronic rheumatism chiefly the large, joints. Moreover, chronic interstitial nephritis and arteriosclerosis, with their varied and often serious consequences, are frequently attendant upon gout, but not upon chronic rheumatism.

To differentiate chronic gout and *rheumatoid arthritis* is sometimes a hard problem, but the following table will indicate the main points of difference:

GOUT.

Frequently hereditary.
 Causes are chiefly dietetic.
 Affects males and the better classes most frequently.
 Begins in the big toe and extends to other toes; it is unilateral.
 Attacks are periodic.
 Deformity due to tophaceous deposits.
 Uric acid in excess in the blood.
 Complications (nephritis, arterio-sclerosis).

ARTHRITIS DEFORMANS.

Not so.
 Causes chiefly nervous.
 Affects females and lower classes most frequently.
 Begins in the fingers, which point to the ulnar side; develops in symmetric order.
 More steadily progressive.
 Deformity due to exostosis and ankylosis, and more marked.
 Not so.
 Very rare.

Treatment.—(1) **Prophylaxis.**—In order to prevent the development of gout, especially in persons who have inherited or acquired a strong predisposition to the disease, temperate and even rigid habits of living should be adopted. Alcohol, particularly the heavier wines (Madeira, port, sherry, champagne, etc.) and heavier malt liquors, must be eschewed, and the patient must eat sparingly of concentrated meat (particularly red meat). A residence in the country with active out-of-door exercise is of paramount importance, but straining efforts, both mental and physical, are to be avoided. The climate should be temperate and moderately dry. The sleeping apartments should be capacious, well ventilated, and free from draught, and the action of the skin is to be favored by cleanliness, and if the patient be strong by a cold bath in the morning with friction. For the robust, Turkish baths at intervals of two or three weeks constitute an excellent measure. In debilitated patients warm baths on retiring are preferable, and the chilling of the skin-surface is to be carefully guarded against. The patient should wear flannels.

(2) **Active Treatment.**—(a) *Dietetic.*—"There is no diet for gout, but there is a diet for the patient" (H. C. Wood). The amount of food must be lessened as a rule, and taken at regular intervals. On the other hand, spare gouty subjects are met with, and in such I have found a generous diet, including fat-producing foods, of great service. During an attack we should attempt to overcome the perverted metabolism of the liver and gastro-intestinal tract, and to minimize the production of the purin bodies. Broadly speaking, the dietary should be constituted as follows: *succulent vegetables* (cabbage, salads, string-beans); *fruits* (except bananas, tomatoes, and strawberries); *farinacea*, as rice, hominy, and the like (oatmeal to be avoided); *meats* should be restricted; beef and mutton in moderation may be allowed except in well-marked cases of gout; oysters and fish (except those that contain too much protein, salmon, smoked herring, canned sardines, mackerel, halibut, salt codfish, flounder), and fowl, particularly the white meat of chicken, are permissible; *fats* in the form of good butter may be taken freely—from $2\frac{1}{2}$ to $3\frac{1}{2}$ ounces (70.0–100.0) per diem, according to Ebstein; *milk* is entirely unobjectionable, and should be used in large quantities. If whole milk does not agree, it may be mixed with an equal part of Vichy. According to Kolisch, eggs are not objectionable, as the nucleins contained do not form alloxins. *Stale* breads may be used. Occasionally patients do best on albuminoids, while, on the other hand, with about equal frequency they improve on a vegetable diet; but a mixed diet is best adapted to the vast majority of the

cases. Among articles to be avoided are pastry, tea and coffee, hot bread and cakes, sweet puddings, cheese, dried meats, and all highly seasoned dishes.

Beverages.—Alcohol is ordinarily to be interdicted. Rarely it becomes necessary to administer it, particularly in cases of suppressed gout, and when needed whiskey or gin (diluted) is to be preferred. Champagne, Tokay, Port, and malted liquors are particularly injurious in their effects, but clarets, Rhine, and Moselle wines can be generally taken without unfavorable results.

Mineral waters, particularly the alkaline, are highly advantageous, and sometimes are even curative. Their value, like that of the warm baths and systematic exercise, is dependent upon their power to increase renal elimination. Whether they promote solubility of the uric acid in the blood is questionable; moreover, according to the observations of Klemperer, this is not a rational indication. The carbonate and citrate of lithium are efficient diuretics, but have no other claim to virtue in this disease. Among natural waters of special value abroad are Vichy, Carlsbad, Homburg, Ems, Kissingen, Aix, Buxton, and Bath, and in this country Saratoga and Bedford. These waters are to be taken in large quantities and when the stomach is empty. It is highly probable that the environment, rigid system of hygiene, including exercise and an appropriately modified dietary, play the principal rôle in producing the favorable results obtained at these noted springs.

(b) *Medicinal Treatment.*—During an acute attack the pain, if excruciating, is to be relieved by a hypodermic injection of morphin, which is to be followed by a purgative dose of some mercurial. Colchicum is the specific remedy, and must be administered, in the form either of the wine or the tincture, in doses of \mathfrak{m}_{xx-xxx} (1.333–1.999) every four hours. It alleviates the inflammation and promptly relieves the pain, but its effects during the attack should be carefully noted. The salicylates may also be given to relieve pain. After the paroxysm it should be continued, though in small doses, combined with the citrate or bicarbonate of potassium or lithium. The limb should be raised and the affected joint or joints wrapped in flannel or cotton-wool. Warm alkaline solutions or hot fomentations often afford relief in the worst cases, and anodynes may be tried locally. The diet should consist chiefly of milk, animal broths, and egg-white during the attack, later rice, eggs, fish, and other light forms of meat may be added, the more liberal dietary previously indicated being slowly resumed.

In the *intervals* between the acute attacks the prophylactic and dietetic measures previously mentioned are to be resorted to, in order that recurring paroxysms may be prevented, and in addition the alkaline diuretics and saline laxatives, together with warm bathing, will be found of value. Hepatic stimulants yield good results.

In *chronic* and *irregular forms* of gout medicines are of subsidiary importance, and are in no wise comparable in their beneficial effects to the previous recommendations. Piperazin has been warmly advocated in all forms of gout for its supposed effect as a solvent of uric acid, and clinicians are almost unanimous in reporting its favorable results. Its beneficial effects are probably due to its diuretic action. The dose is gr. v–x (0.324–0.648) thrice daily, freely diluted with water. The late Sir William Roberts recommended potassium bicarbonate (3ss—2.0, in a tumbler of water at bedtime) to stem the nightly acid tide. Some authors highly recommend the salicylates for acute attacks of gout, both pri-

mary and intercurrent, in the course of the chronic form. In my own experience they have been less effective in this disease than colchicum. Benzoic acid and colchicin have a double action in that they stimulate the hepatic circulation and also "bind the glyocol, thus preventing it from precipitating the uric acid in the organism."¹ C. von Noorden and L. Schliep² have shown that there is a certain tolerance for nucleins in gout; and in every case its exact degree should be determined by allowing a definite number of grams of meat per diem and extracting the uric acid, the diet being restricted accordingly. Luff has demonstrated by experimentation the negative value of the alkalies and salicylates in the treatment of gout. If nephritis or a failure of compensation be present, even the former remedies should be administered with extreme caution.

For *chronic gout* potassium has been much used, though with slight advantage to the patient, I think. Fenner lauds a sterilized solution of thymic acid (gr. ij—0.13) by intramuscular injection, in subacute and chronic forms of podagra. A small dose (gr. iv—0.26, daily) after meals for three months and then every alternate week, tends to avert the onset of acute symptoms. The bitter tonics, combined with a vegetable salt of iron, as well as change of climate, should be resorted to in the anemic, debilitated class of gouty patients.

LITHEMIA.

Definition.—A condition due to a disturbed cellular metabolism. It is characterized chemically by an excess of uric acid in the blood, and clinically by various digestive, circulatory, genito-urinary, and nervous phenomena. My purpose in describing lithemia is that the common error may be avoided of attributing its symptoms to other causes.

Pathogenesis and Etiology.—Lithemia is comparatively a latent condition. There is an *excess of uric acid*, which may be for a time eliminated through the natural channels (kidneys, lungs, skin, etc.) without the occurrence of symptoms. On the other hand, when, as the result of too little exercise, impaired elimination, luxurious living, the use of sweet wines, combined with the neurotic temperament, uric acid is allowed to collect in different parts of the organism, marked disturbances—nervous, gastro-hepatic, etc.—follow. Da Costa defines lithemia as a condition in which "the income of nutriment is in excess of the output of waste." C. G. Stockton holds that lithemia is a gastro-intestinal auto-intoxication. Among agencies that *predispose* are alcoholism, heredity, climate (temperate or cold climates favor diminished action of the skin), and the male sex.

Symptoms.—The nervous, circulatory, respiratory, integumentary, and genito-urinary symptoms are practically the same as those described under Irregular Gout; but I would here emphasize the broad clinical fact that the urethral and genital mucous membranes often become inflamed on slight provocation, producing urethritis, cystitis, orchitis, epididymitis, vaginitis, endometritis. These conditions resist treatment.

Gastro-intestinal Symptoms.—The appetite is variable, sometimes voracious, and at other times it is impaired or perverted. The tongue is coated, and a metallic taste is often complained of, while various forms of indigestion attend. There may be a delay in the conversion of the

¹ H. Kionka, *Deutsch. med. Woch.*, July 20, 1905.

² *Berlin. klin. Woch.*, October 9, 1905.

albuminoids, causing *pyrosis*, *gastric oppression*, *fulness*, and sometimes nausea and vomiting soon after food. These symptoms, together with *marked flatulence*, are manifested at a later period after meals if there be failure in the digestion of the carbohydrates. The bowels work irregularly, and there may be diarrhea attended by colicky pain, with frothy and ill-smelling discharges. Hemorrhoids are usual, and melena may occur independently of the hemorrhoids. The liver is somewhat enlarged and often tender. A few prominent **cardio-vascular symptoms** should be mentioned, such as *palpitation*, particularly after eating, or lying abed. *Increased arterial tension* may develop early, and is due probably to the action of toxins in the blood upon the vaso-motor nerves, exciting universal contraction of the arteries. This condition often leads to arterio-sclerosis and sooner or later the well-known clinical group—chronic gout, arterio-sclerosis, and granular kidney—will be presented.

Treatment.—(1) **Prophylaxis.**—The patient should be taught the lesson of thorough mastication, and robust, plethoric persons should exercise with method in the open air, with a view to consuming the fats in the body. For this purpose cycling, horseback-riding, rowing, and walking are all excellent. Nervous persons, however, demand rest (Gray). The constant use of lithia-water, more particularly in the spring of the year, is warmly advocated by Wilcox.

(2) **Diet.**—As in gout, so in the preliminary stages of lithemia, no single dietary suits all cases, though I agree with those who contend that a diet consisting chiefly of albuminoids is proper in most cases. The lighter forms of albuminous articles of diet are to be preferred, and, if well borne, fruits and green vegetables may be added; but fried meats of all sorts and made-over dishes are to be eschewed. Assuming that certain cases are dependent upon an auto-intoxication from the gastrointestinal tract, the object should be to limit fermentation by the use of a nitrogenous diet; and I have found large amounts of water very beneficial in such instances. There are cases in which the gastric digestion is feeble, and in such the carbohydrates are better borne than the albuminoids. Cream and good butter are the only forms of fat to be allowed. Alcohol should be interdicted.

(3) **Medicinal Treatment.**—If the patient be robust, it is well to begin with a saline laxative, such as Carlsbad Sprüdel salt (3j—ij—4.0–8.0), moderately diluted and taken before breakfast. If necessary, the hepatic function may be stimulated still further by a mild mercurial or by podophyllin. On the other hand, the neurasthenic, delicate sufferer must use a milder form of laxative, such as Rochelle salt in the same dose, or sodium phosphate in the morning, or a rhubarb pill at night. This class of lithemics also requires nerve-sedatives (sodium bromid, etc), and diuretics to aid in the excretion of uric acid. If it be true, as some claim, that the sodium phosphate is for the greater part excreted by the urine, and that it holds in solution more uric acid than any other salt, it is one of the foremost remedies in the treatment of the affection. Personally, I have found it to be a most useful agent. To reduce acidemia and to stimulate gently hepatic activity the salts of lithium, highly diluted, may also be tried. To aid in the digestion of the albuminoids hydrochloric acid may be needful, and if the appetite be impaired it may be combined with a simple bitter or with *nux vomica* (℞x—xv—0.666–9.999) thrice daily.

RACHITIS.

(Rickets.)

Definition.—A constitutional disorder of childhood, exhibiting developmental anomalies, chiefly in the bones and cartilages, causing deformities.

Pathology.—A mere summary of the anatomic characters can be given here. There is a derangement of the nutritive processes which retards and otherwise modifies the growth of the bony skeleton, particularly of the skull, the ends of the ribs and of the long bones. The latter soften or remain unduly flexible as the result either of the absorption of ossified structures or of the greatly diminished deposition of lime-salts. Longitudinal section of the long bones shows the seat of the chief changes to be at the junction of the epiphysis with the shaft. In health we note at this point two thin layers, an outer (next to the epiphyseal cartilage) proliferative zone, and an inner layer (of ossification). In rachitis both zones, though more particularly the proliferative, are greatly thickened, much softened, and their margins irregularly notched. The periosteum is thickened and easily separable from the shaft.

A *microscopic* examination shows an increased rate of proliferation of the cartilage-cells with a scanty, fibroid matrix, while the ossific layer presents disseminated and imperfectly calcified areas. Similarly, the deep (osteoblastic) layer of the periosteum is thickened, and remains spongoid. It is highly probable that absorption of true bone-tissue rarely occurs, and that the most characteristic pathogenic change is a lack of development of the normal structures. The morbid changes probably arise, as Kassowitz contends, from the presence of hyperemia of the cartilage, marrow, and periosteum—a process that interferes with the deposition of lime salts.

The cranial bones present areas of the so-called craniotabes, and yield to the pressing finger in consequence of delayed ossification. This may lead to a disappearance of the cranium in certain areas, causing depressions, while flattened protuberances may develop over the arterio-lateral regions. When cases terminate in recovery the bones become hard and ossify, although the deformities persist. The chemist has shown us that rachitic bones may contain less than half the normal percentage of lime-salts. The liver and spleen are moderately enlarged, and rarely the mesenteric glands are increased in size.

Etiology.—(1) Rachitis may occur in the *new-born*. Schwartz states that among 500 new-born children in Vienna, 75.8 per cent. show distinct signs of rachitis. Doubtless this estimate is too high, and entirely at variance with the experience of clinicians in general; but I believe that congenital rickets is by no means a rare condition. Many of the cases are still-born, and those that outlive childhood become peculiarly dwarfed (*micromania*). (2) *Heredity*.—The instances in which rachitis develops at an early period of life, due to ante-partum causes, are not rare, but it must not be forgotten that it is extremely hard to estimate the influence of heredity where both parent and child are exposed to similar unfavorable hygienic and dietetic conditions. Ill-health, malnutrition, close confinement, lactation, and syphilis may all act as predisposing factors during pregnancy. Setting aside syphilis, and perhaps phthisis, the state of

the health of the father has little if any effect in the causation of rachitis in his offspring. (3) *Geographical Distribution*.—The disease is more common by far in large cities than in rural districts, and in European countries—Russia, Germany, Great Britain, and Italy more especially—the disease prevails more extensively than in America. (4) *Race*.—The colored race furnishes a preponderance of rachitic subjects. The reason for this may be a racial need of warmth that is not supplied by the temperature of more northerly latitudes, their native habitat being in a more southerly climate. The Italian race also suffers inordinately. (5) *Station*.—It is especially among the ranks of the poor children, whose environment is highly unfavorable, in large cities that rachitis is seen. Joukowsky, from personal observations in over 3000 poor children in St. Petersburg examined for rachitis, found that from the working-classes come the greatest number of cases. Like scurvy, rickets may be found in the families of the wealthy under perfect hygienic conditions (Osler). The quarters of the cities in which the poorer classes live are densely crowded, the dwellings are insufficiently ventilated, and there is a great lack of sunlight. (6) *Diet*.—The disease is dependent largely upon unsuitable or insufficient food; and among hand-fed children, especially if the milk is sterilized, the disease is much more common than among those at the breast. It also occurs in breast-fed infants when the mother's milk is poor in quality as the result of previous ill-health or too long-continued lactation. The view was at one time widely held that rickets was produced by a farinaceous diet, and that the active agent was lactic acid, produced by the fermentative processes set up by the starch. Even granting, however, that the lactic acid forms a soluble salt by union with the lime of the bone, thus removing it from the system, this does not explain the productive lesions described under Pathology. According to another view, which is supported by experimental proof, rachitis is apt to develop when the amount of both proteids and fats is low. Certain forms of diet predispose to rickets, principally for the reason that they do not supply certain necessary articles in adequate proportion. (7) *Age*.—Of 903 cases, more than 75 per cent. occurred before the end of the second year; but of these only 99 commenced during the first half year (Bruennische, Von Rittershain, Ritsche). It may occur as late as the tenth year. (8) *Sex* is without effect. (9) *Syphilis*.—Divers views are entertained regarding the rôle played by syphilis as a cause of this disease. It cannot be denied that syphilis brings about a marked impairment of nutrition, so that the disease may engender a predisposition to rickets.

(10) Findlay¹ attributes rickets to lack of exercise and confinement.

Bacteriology.—Mircoli contends that it is produced by the action of ordinary pyogenic organisms upon the osseous and nervous systems.

Symptoms.—The onset is *slow*, and the symptoms of gastro-intestinal catarrh, with their usual effect upon the general nutrition, may precede or accompany the true rachitis symptoms. At the beginning the infant is restless, irritable, and sleeps poorly, and slight fever is present in some cases. About the head and neck the child perspires freely, especially when asleep, wetting his pillow while the rest of the bed is dry. It is also annoyed by the bed-clothes, which it continually throws off,

¹ *Boston Medical Journal*, July 4, 1908.

lying exposed even in a cool temperature. Among the *earlier symptoms* is a tenderness both over the bony surfaces and the soft parts, so that the patient wishes to keep still and dreads to be handled. The child is languid and disinclined to move his limbs or to walk or play, even if he have done so previously.

The symptoms are progressive in their development, rachitis being ordinarily a chronic disease, so that after many months more pronounced features, including various bone-deformities, appear. Owing to the impairment of nutrition of the muscles the use of the limbs may become impossible, and these cases have been spoken of by writers as "rachitic paralysis;" this, however, is a misnomer. Cases have been reported by Berg and others that resembled spastic paralysis, pseudo-hypertrophic paralysis. Urinary phenomena are neither constant nor characteristic. Secondary anemia of mild grade supervenes, the hemoglobin often being comparatively low, and there may be a leukocytosis.

The first rachitic *osteal changes* are presented by the cranial bones, the ribs, the radius, and the ulna. The cranium appears enlarged, though this enlargement is more apparent than real, being due to the diminished size of the facial bones. The sutures remain open, the fontanels are large, and their closure is delayed, sometimes until the fifth or even the eighth year. *Craniotabes* is most frequently seen in infants under one year of age. This soft, thin condition of the bones is due to pressure both from within and without; it occurs on the surfaces on which the head of the child rests while lying. To detect the presence of craniotabes light pressure with the fingers is to be made in a direction away from the sutures. It is to be recollected that craniotabes is often a syphilitic manifestation. *Per contra*, increased hardness of certain bones may be observed (cranio-sclerosis). A *rachitic head* generally approaches a square in outline, or it may present marked angularities, with an increase in the antero-posterior diameter and a flattened top. Hyperostosis may cause prominence of the parietal and frontal eminences, giving the forehead a square, broad outline. A short, round head (brachycephaly) may rarely be met (Bonnifay). The veins of the scalp are enlarged, and the hairy growth is usually scanty, being often removed from the back of the head by rubbing. Drs. Whitney and Fisher first called attention to the fact that the ear placed over the anterior fontanel often detects a systolic murmur. A considerable patency of the anterior fontanel both in health and disease allows of detection of this murmur, however, and hence its diagnostic value is slight. A prominent feature of the disease is delayed teething, the teeth that appear being deficient in enamel, ill-shaped, although not prone to decay.

The *ribs* early become beaded. Anteriorly, where they join the costal cartilages, swellings occur, causing the "rachitic rosary." This is composed of nodules corresponding with the costo-chondral articulations, and these can generally be seen and always felt under the skin. They rarely outlast the fourth or fifth year. The ribs present two short curves—one at the junction of the dorsal and lateral parts of the thorax, and the other in front, where they turn sharply inward toward the sternum. This deformity is the result of the atmospheric pressure upon the softened bones, a shallow groove usually being produced in the line of the costo-chondral articulations or obliquely from the second or third rib downward

FIG. 33.—Outward curvature of tibia and fibula (Willard).

and outward. These changes lessen the transverse diameter of the thorax in front and interfere with the lung-expansion in the antero-lateral portions of the chest. They also produce bulging of the sternum, resulting in the so-called *pigeon* or *chicken breast*. On both sides, from a point corresponding to the anterior end of the eighth or ninth rib, there passes outward toward the axilla a furrow (Harrison's groove) which is caused by an eversion of the lower part of the thorax, and is heightened by atmospheric pressure, particularly during inspiration. This thoracic deformity is not peculiar to rickets, but is met with in all cases in which there is moderate obstruction to the ingress of air into the lungs.

Among the first indications of rickets is an enlargement of the lower end (junction of the shaft and epiphysis) of the *radius*. The radius and ulna are sometimes twisted and deflected outward, owing to the fact that some of the body-weight is supported by the hands when sitting or crawling. The clavicle may be thickened and curved near either end, and occasionally the scapulæ may be enlarged, but deformities of the upper extremities are rare as compared with those of the lower. Occasionally the vertebræ and intervening cartilages soften, with a resulting spinal curvature, usually antero-posterior.

Pelvic deformities are not uncommon, and are of no little importance in female children as bearing upon the questions of marriage and subsequent labor. The femora may be curved, often forward and more rarely outward; swelling of the lower end of the tibia is, however, the first change to be observed in the lower extremities. In some well-advanced cases the heads of the bones forming the knee-joints are also enlarged, and outward curvature of the femora and tibia is common, especially under the age of one year (see Fig. 33). After the child begins to walk a forward bowing of these bones, due to the weight of the body and to muscular action, occurs. Knock-knee is sometimes observed. Those who have suffered from rickets in infancy usually fall short of the average stature on reaching adolescence, giving rise to disproportion between head and height.

These skeletal changes sustain a causal relation to many, and some serious, affections, chiefly *nervous*. Thus, *craniotabes* is supposed to induce *laryngismus stridulus*, though this condition may also arise in the rachitic without cranial softening. Rickets also predisposes to *tetany*, which affects most commonly the upper extremities. Convulsions are prone to occur in this disease. The reflex nervous excitability is unquestionably exaggerated in rickets, and another cause for the eclampsia often met with is the associated gastro-intestinal catarrh. The abdomen becomes greatly enlarged, chiefly by flatulence, though to a less extent also by the swelling of the *liver* and *spleen* (passive congestion). Wm. Ewart¹ has recently called attention to the importance of abdominal atony and distention in rickets; it interferes with circulation and respiration. *Chest-complications* due primarily to interference with the cardio-pulmonary circulation, and the respiration, are common. Among these are atelectasis, bronchial catarrh, broncho-pneumonia, and emphysema. Anemia, when present, may be accounted for by some complication. *Green-stick fracture* of the bones often occurs in the rachitic subject.

Diagnosis.—Says Holt: "The most important early symptoms for diagnosis are sweating of the head, *craniotabes*, great restlessness at night, delayed dentition, and enlarged fontanel. All these, taken

¹ *Brit. Med. Jour.*, Oct. 13, 1906.

separately, may mean something else, but collectively they can mean nothing but rickets." At a later period the beading of the ribs and other characteristic deformities are usually present.

Prognosis.—The evolution of rickets is a long process; hence most patients become weak, anemic, and emaciated. The so-called "fat rickets" is not rare. Innately, the disease tends to spontaneous cure, which is attained from the end of the second to the fifth year; but its course may be abridged to a few months by appropriate treatment. When death occurs, it is usually occasioned by one or other of the complications before mentioned (laryngismus stridulus, pneumonia).

Treatment.—**Prophylaxis.**—Simple means directed to the antepartum causal factors in the mother may in a large proportion of the cases be preventive of rickets. Prophylaxis also embraces appropriate feeding and other agencies that tend to maintain the normal nutrition of infants.

Hygienic Management.—*Proper feeding* is an important factor, and if the child cannot be satisfactorily nursed by its mother and if it is under the age of six months, a wet-nurse should be procured. Should this not be practicable, it must be hand-fed, and the best artificial food is cows' milk, if properly prepared. It is diluted to suit the age, and I have found that barley-water, when made in the manner recommended by J. Lewis Smith, may be added to milk, replacing the water most advantageously. A heaping teaspoonful of barley-flour is poured into 25 teaspoonfuls (3ij—96.0) of water, and when the mixture is lukewarm 10 or 15 drops of diastase (Forbes) are added to it, the gruel in a few minutes becoming much thinner from the digestion of the starch. The physician must regulate with much precision the frequency of the feeding, and the amount of food taken according to the age of the child. The stools are also to be inspected. If they are green or if curds appear, either digestion is imperfect or the child is being over-fed. Older children may be given the lighter meats, freely, green vegetables, and fruits, but these must be carefully selected.

Other *hygienic details* are of little less importance than a proper diet. The decubitus of the child must be changed frequently, so as to prevent bony deformities; moreover, the rickety child should not be allowed to walk, and to prevent his doing so splints extending beyond the feet have been recommended. A tepid bath, warm clothing, and a prolonged daily stay in the open air are measures that should not be neglected.

Of *medicines*, those that rank highest are phosphorus, the hypophosphites, iron, and cod-liver oil. The officinal oleum phosphoratum (gr. $\frac{1}{150}$ —0.0021) is used by Jacobi. Phosphorus is highly spoken of by many writers. It may be given either pure (gr. $\frac{2}{100}$ to $\frac{1}{100}$ —0.0003 to 0.0006) or preferably in the form of an emulsion with sweet oil or cod-liver oil:

R. Phosphori, gr. $\frac{1}{10}$ (0.00648);
Olei olivæ, 3ij (64.0);
M. et ft. emulsio.

Sig. 3j three times a day, after meals, for a child under the age of one year.

Kissel states there is no evidence in favor of the use of phosphorus in rickets. Baginsky, Leray, Weiss, and others have found from its

extensive employment that it is of doubtful value in the majority of cases. Kassowitz, Swetchen, and others, however, observed cases with cure, hence the remedy deserves a trial.

When it is desired to administer cod-liver oil and it is not tolerated by the stomach, it may be rubbed gently into the skin of the thighs and trunk. Arsenic in small doses has proved to be a capital remedy in selected cases; and iron, particularly in combination with arsenic, is indicated if anemia be pronounced.

The numerous *complications* to which rachitic subjects are liable present special indications which are to be met by the same measures as when they arise under other circumstances. The condition of the digestive organs must be kept constantly in mind; and no remedy, however promising, that is designed to assist the general condition should be continued if it tends to aggravate the digestive disturbance. Ewart advises massage for the abdominal atony and also the use of an elastic belt which gives support to the abdominal parietes and improves circulation and respiration. The treatment of the rachitic deformities belongs to the domain of the orthopedic surgeon and should be undertaken early.

SCORBUTUS.

(*Scurvy.*)

Definition.—A constitutional disorder, dependent upon dietetic errors, and characterized by anemia, excessive weakness, spongy gums, a tendency to muco-cutaneous hemorrhages, and a brawny induration affecting chiefly the muscles of the calves and the flexor muscles of the thighs. Scurbutus and rickets, distinct affections, often coexist.

Pathology.—We know nothing concerning the pathogenesis of scurvy. Evidences of profound anemia are found upon microscopic examination of the blood, which is thin and dark, but there is no leukocytosis. The skin may show spots of subcutaneous hemorrhage (ecchymoses), but the most characteristic hemorrhage is that under the periosteum of the femora. Bleedings into the articulations and muscles may also at times be noted, and occasionally the serous membranes are the seat of hemorrhages, as well as the internal organs. Submucous hemorrhages are extremely common. The intestinal mucosa may also present ulcers. The gums are swollen, spongy, dark in color, and sometimes ulcerated, and the teeth may be loose or missing. The epiphyses, particularly of the lower end of the femora, may be congested, and even detached. The spleen is soft and swollen. The heart, liver, and kidneys sometimes show fatty and often parenchymatous degeneration.

Etiology.—**Incidence.**—In former times scurvy was very prevalent among sailors at sea and soldiers in the field, and epidemics were common. Doubtless, however, it has declined in importance as a disease incident both to sea-life and to armies; but, as pointed out by Wise, it would seem that changing physiologic and economic conditions may cause it to be dreaded on the land as it has hitherto been on the sea. Osler states that the disease is not infrequent among Hungarians, Bohemians, and Italian miners in Pennsylvania. It is rarely *epidemic* at the present day. F. A. McGrew records an epidemic

(with a total of 42 cases) in Chicago, in 1894. *Endemic* appearances of scurvy are still common, particularly in portions of Russia (Hoffman) and elsewhere also, sweeping through prisons, barracks, almshouses, and other institutions of like kind. While the majority of cases met with are sporadic, the above facts point to the infectious character of scurvy. Russell contends that adult scurvy is caused by lime starvation.

Bacteriology.—Testi and Beri have isolated a micro-organism which has been cultivated and inoculated into guinea-pigs and rabbits, producing in the latter pathologic lesions and symptoms simulating closely those of scurvy. The microbe is perfectly round and is a diplococcus. These experiments require confirmation.

Predisposing Causes.—The chief factor is an unsuitable dietary long continued. The absence of the organic (potassium) salts present in fresh vegetables disturbs normal histogenesis. Albertoni has recently shown that in scurvy of a protracted course free hydrochloric acid is absent from the gastric juice, and that the total acidity is much reduced, but this is so neither in every case nor at all stages of the disease. He found no deficiency of chlorids in the body. Peptonization is feeble. It may be a true toxemia.

Debilitating influences, as unhygienic surroundings, excessive muscular exercise, humidity, and cold, often play no mean role in causing scurvy. Mental anxiety and depression seem to have etiologic significance. The old are very susceptible, and all ages are liable to the disease. *Sex* has no special influence upon scorbutus. Starvation does not predispose to the disease.

Symptoms.—Scurvy has a *slow* onset. The earliest symptoms are generally a swelling around the eyes, over which the skin has the color of a bruise, and a pale face, which looks bloated and wears an apathetic expression. There is noticeable almost from the start a gradually increasing debility, emaciation, an inability to perform mental or physical labor, and despondency. The patient experiences arthritic and muscular rheumatoid pains and dyspnea on slight exertion.

With rare exceptions the *gums* swell, sometimes enormously, and become spongy, bleeding most readily. They may become ulcerated, and may be, though rarely, fungoid in appearance. The *teeth* often become loose, and in rare cases drop out. The *breath* emits an offensive odor, that is sometimes due to necrosis of the jaw. The *tongue* swells, though it is usually clean and often pale. In the mouth may be observed submucous hemorrhages in many cases. There is loss of appetite, but the digestion is usually good; there may, however, be constipation or diarrhea, more frequently the former. *Scorbutic dysentery* has been described by certain writers. The *skin* is dry and of a muddy color, blended occasionally with a greenish or greenish-yellow tinge. At the end of a week or ten days *petechiæ* and *ecchymoses* appear upon the legs, arranging themselves about the hair-follicles. These may also come out later on the trunk and upper extremities. Submucous hemorrhages may give rise to circumscribed swellings, and *subperiosteal hemorrhages* may occur and engender node-like protuberances. There may be frequently noticed a peculiar brawny induration, due to extensive hemorrhagic infiltration of the muscles and subcutaneous tissues, most marked in the hams and calves. The condition is not without considerable *pain*, particularly

if the parts be touched, and in severe cases bullæ and vibices may be seen, as in a recent case of my own. Hemorrhages from the mucous channels of the body occur, and epistaxis is frequent. In bad cases hematuria, also melena and rarely hematemesis, may be observed. Blood may be effused into the serous membranes, accompanied sometimes by inflammatory changes in the latter; also into the lungs, which are rarely the seat of secondary pneumonia. Pulmonary infarction occurs, but is a rare event. Hemoptysis may be a symptom of the lung-complications or may occur as an independent phenomenon.

The *heart* may present symptoms, such as palpitations, feeble impulse, arrhythmia, and sometimes a basic blood-murmur, but these are without diagnostic importance. The pulse is soft, small, and on exertion much accelerated. The *temperature* is sometimes subnormal, and the presence of fever is a certain indication of the existence of some complication.

The *nervous symptoms*, aside from the profound mental depression, are not prominent. Insomnia may be a distressing symptom. Delirium (late) is sometimes witnessed. Meningeal hemorrhage may supervene. Both night-blindness and day-blindness are among the rarer and extraordinary ocular features.

The *urinary symptoms* vary in different cases. Albuminuria is common. The specific gravity of the urine is increased, the color high, and solid constituents diminished, except the phosphates, which are abundant. Albertoni found the proportion of chlorids less than the normal, while other investigators claim that the percentage is high. *Nephritis* may occur as a complication. The bones in long-standing cases may be congested and sometimes necrotic, and the epiphyses may separate from the shafts. In one of my cases an old cicatrix reopened.

Diagnosis.—This rests upon the following points: the history, the peculiar facies, the spongy and swollen gums, the gingival and deep-seated cutaneous hemorrhages, the progressive loss of strength and energy, great mental depression, and the speedy recovery after an appropriate regimen. Scurvy will be distinguished from *purpura* under the description of the latter disease.

Prognosis.—Unless far advanced, the prognosis generally becomes good upon the institution of correct dietetic principles. If the disease have made extensive inroads, the danger to life is considerable. The gravity of the internal symptoms (particularly pulmonary) is far greater than of the external, and, indeed, the presence of the latter is a favorable omen. Certain complications augur a serious termination, such as pneumonia, hemorrhagic infarctions of the lung, pleurisy with bloody effusion, dysentery, acute nephritis, etc.

Treatment.—**Prophylaxis.**—By carrying out the known means of prevention the disease has been diminished more than 90 per cent. among mariners and soldiers. This change has been brought about by the enforcement of governmental regulations which demand that an adequate supply of antiscorbutic articles of food must be provided for military campaigns and for long sea-voyages. Fresh fruits and vegetables can be readily transported in hermetically sealed jars or cans.

Treatment of the Attack.—The chief indication is to be met by the use of fruits and fresh vegetables. Of the former, two or three

lemons daily or oranges and other fruits suffice to work a surprising degree of improvement in a short space of time. Antiscorbutic vegetables (potatoes, water-cresses, raw cabbage, lettuce, saur-kraut) in liberal quantity should also be given. Meats, eggs, milk, and farinaceous dishes are not to be prohibited, since the patients require all forms of food to invigorate the system and to render normal the constitution of the blood; but if the digestive power be feeble, it is advisable to begin with the juice of oranges or lemons, conjoined with meat-juice, egg-white, milk, and light farinaceous articles, adding the stronger forms of animal food and fresh vegetables when improvement is noted. We may assist the digestive function in bad cases by the use of simple bitters, strychnin, and hydrochloric acid (after meals); hematinics are sometimes indicated.

Special symptoms may call for appropriate measures. Constipation requires simply an enema. On the other hand, diarrhea presents an indication for intestinal antiseptic and astringent remedies. The oral condition varies, hence the measures to relieve it vary also; but if ulcers be present, the solution of potassium chlorate is best. For swelling of the gums the application by means of a cotton swab of tannic acid (2 per cent.) or a solution of silver nitrate (2-5 per cent.) is serviceable. A combination of boric and carbolic acids in a solution of suitable strength may be used as a mouth-wash. If copious hemorrhages occur, hemostatics are eminently useful. The various complications must be met by the usual measures, according to their nature.

INFANTILE SCORBUTUS.

(*Barlow's Disease.*)

Definition.—A constitutional disease, characterized by the same symptoms as scurvy in adults, except that in many instances undoubted evidences of rachitis are associated.

Pathology.—The bones are thickened and excessively sensitive, owing to a marked subperiosteal hemorrhage, with more or less maceration, and want of firmness between the epiphysis and shaft. The muscles may also be the seat of effusion. The characteristic lesions of rickets are often associated.

The *nature* of the affection is unsettled. Originally looked upon by most observers as acute rickets, it was subsequently described by Cheadle (from the clinical side) and Barlow (from the anatomico-pathologic side) as infantile scurvy. On the other hand, Ashby of Manchester, Fürst and other German writers, are inclined to the view that the affection should be considered a hemorrhagic form of rachitis. The belief that rickets predisposes to scurvy, but that the two diseases have not the same pathogenesis, is probably the correct one.

Etiology.—Scurvy is largely confined to *hand-fed infants*, especially those reared upon the numerous infant-foods which have been foisted upon the market, including condensed milk, etc. Louis Starr, Jacobi, and others have shown that it sometimes follows the prolonged use of sterilized milk, although the etiologic importance of the latter food has been too much emphasized. Concetti¹ concludes that infantile scurvy is caused by alimentary intoxication. An investigation by a committee of the American Pediatric Society² showed that of 379 cases the majority

¹ *Archiv f. Kinderheilk.*, April 17, 1909.

² *Medical Record*, July 2, 1898.

occurred between the ages of 7 and 14 months, inclusive, and that the disease has a greater tendency to occur among the rich or well-to-do. This committee's report also embraces the following among other justifiable conclusions: "The farther a food is removed in character from the natural food of a child, the more likely its use is to be followed by the development of scurvy."

Symptoms.—The *skin* presents the muddy color peculiar to the disease in adults. The patient may be well nourished, but more often there is a tendency to *wasting*, and other symptoms of impaired nutrition appear, particularly irritability and disinclination to exertion. The more characteristic features appear after one or two months, and the child cries when handled, especially on touching the lower limbs. About the same time there is an irregularly cylindrical swelling of one of the thighs, due to subperiosteal effusion. Soon the other limb is similarly involved, though not always to a like degree. At first the legs are flexed, but later they become straightened and slightly everted on account of the progressive hemorrhage or separation of the epiphyses. The bones in other portions of the body may be involved secondarily in more or less rapid succession, but the swellings are less marked than in the lower limbs. Later, if teeth be present, the gums may swell and become spongy. Ecchymoses in the form of petechiæ appear upon the skin-surface, and particularly about the eyes. Barlow describes a remarkable ocular phenomenon: "There develops a rather sudden swelling of one eyebrow, with puffiness and very slight staining of the upper lid. Within a day or two the other lid presents similar appearances, though they may be of less severity. The ocular conjunctivæ may show a little ecchymosis or may be quite free." Hemorrhages from the mucous surfaces may finally put in an appearance.

Diagnosis.—To distinguish *rickets* from infantile scurvy Barlow's brief though clear aggregation of the characteristics of the latter disease may be quoted: "(1) Predominance of lower-limb affection, in which there is immobility going on to pseudo-paralysis; excessive tenderness; general swelling of the lower limbs; skin shiny and tense, but seldom pitting, and not characterized by undue local heat; on subsidence revealing a deep thickening of the shafts, also liability to fracture near the epiphysis. (2) Swelling of the gums about erupted teeth only, varying from definite sponginess to a minute, transient ecchymosis."

In incipient and anomalous cases there is danger of diagnosing rheumatism when scurvy is really the condition present (Griffith).

Prognosis.—Favorable, even in well-established instances, if brought under the proper regimen.

Treatment.—An antiscorbutic dietary—mother's milk or fresh cows' milk, meat-juice, and orange- or lemon-juice—successfully meets the main indication. If there be systemic exhaustion—a condition that is not infrequent—gentle stimulation with brandy (highly diluted) and an abundance of fresh air are pre-eminent among the measures to be employed. Iron, arsenic, and cod-liver oil may be needful to complete the cure, but usually the simple means already mentioned will prove effective. The limbs, especially the lower, may claim attention. Local treatment, however, is rarely necessary, except there be separation of the epiphyses, when suitable splints are to be applied.

PURPURA.

Two main groups are to be distinguished: (1) **Secondary purpura**, which occurs from a great variety of causes and in numerous affections, in which its clinical significance has been pointed out in appropriate sections of this work. It seems pertinent, however, to enumerate the chief among the diseases and conditions under which it may arise, as follows: (*a*) scurvy; (*b*) acute infectious diseases (typhus fever, ulcerative endocarditis, cerebrospinal meningitis, variola, measles, septicemia and scarlatina, and typhoid rarely; (*c*) hemophilia; (*d*) numerous chronic affections, as nephritis, leukemia, pernicious anemia, jaundice, Hodgkin's disease, tuberculosis, syphilis, chronic alcoholism, and heart disease; (*e*) malignant sarcomata; (*f*) nervous affections, as locomotor ataxia, acute and transverse myelitis, and hysteria; (*g*) mechanical causes, straining efforts, paroxysms of whooping-cough, and violent convulsions; (*h*) certain drugs may produce a petechial eruption—the iodids, quinin, copaiba, belladonna, ergot, mercury, chloral, antipyrin, and turpentine; (*i*) snake-poisons produce rapid and extensive hemorrhagic extravasation (S. Weir Mitchell); (*j*) senile purpura (Bateman), situated chiefly on backs of the hands and along the forearms.

(2) **Primary or idiopathic purpura** forms the second group. It is divisible into (*a*) simple purpura (*purpura simplex*); (*b*) arthritic purpura, of which two varieties may be recognized: (1) *peliosis rheumatica*, and (2) *Henoch's purpura*; (*c*) hemorrhagic purpura (*purpura hæmorrhagica*).

(*a*) **Simple Purpura**.—The cause is unknown. Among predisposing influences, however, is *age*, the condition being most common in children about the time of puberty. It may be a sequel of the acute, infectious diseases, and in not a few cases develops in seemingly healthy subjects.

Symptoms.—This is the mildest variety of primary purpura. The *hemorrhages* into the skin take the form of petechiæ, vibices, or ecchymoses. The first are extravasations of blood in the form of minute points, that appear, as a rule, in the hair-follicles, and, unlike the erythemas, do not disappear upon pressure. The vibices receive their name from the fact that the hemorrhages occur as streaks, while the ecchymoses are larger, but similar in nature and behavior to the petechiæ. They may exceed in size that of a split pea, and their hue ranges from a deep red to a bluish tint. As they fade away they assume at first a yellowish-brown, then a yellow color, and finally disappear. The eruption appears in a series of crops, and its seat of election, often favored by the erect posture, is the legs (*orthostatic purpura*). Bloody serum may be effused into bullæ or large blebs. Shepherd and others have reported cases in which the purpuric eruption ended in gangrene, though in Shepherd's case the gangrene was due to the use of sodium salicylate.

(*b*) **Arthritic Purpura**.—(1) *Peliosis Rheumatica* (*Schönlein's Disease*).—The *cause* of this remarkable disease is unknown. Formerly many writers inclined to the view that it is of rheumatic origin, and since endocarditis and pericarditis are occasionally observed in association with *peliosis rheumatica*, considerable coloring is given to this belief. On the other hand, the fact that the cardiac complications are rare in arthritic purpura shows that not all cases of the latter disease are genuinely rheu-

matic. It occurs chiefly in males from the twentieth to the thirtieth year of age. Among the *prodromata* are angina, slight articular pains, headache, loss of appetite, and fever ranging from 100° to 102° F. (37.7° – 38.8° C.). The affection is especially characterized, however, by *polyarthritis*, the joints being swollen, painful, and very tender; also by purpura, associated or not with urticarial wheals or erythema exudativum; and by subcutaneous edema. The purpuric *eruption* is the only symptom that has pathognomonic significance, and in this affection it shows a strong preference, as regards distribution, for the affected joints and the legs. The eruption, as already intimated, does not display constant characteristics. It may not differ from that of simple purpura, and the rash consists of petechiæ, ecchymoses, streaks, and rarely of bullæ (*pemphigoid purpura*); or it may be made up of wheals of urticaria, attended with intense itching; and, finally, it may be identical with erythema nodosum. These forms of eruptions may be variously combined.

Hemorrhages from the mucous surfaces rarely occur, though epistaxis is the most common. The extent of the *edema* varies greatly, in rare cases being quite extensive and overshadowing all other symptoms (febrile purpuric edema). *Albuminuria* may be noted, and accompanying the purpuric eruption there will be a mild febrile movement. Convalescence is usually protracted.

The *diagnosis* is made from the presence of three characteristic symptoms—polyarthritis, a purpuric rash, and edema. The combination of purpura and urticaria is one of the chief distinguishing features. It is not always possible to eliminate *rheumatism*, but the non-rheumatic character of some of the cases may be clearly shown by the therapeutic test, as happened in one of my own patients.

Prognosis.—This type of the disease is generally benign, death being very rare. Complications, however, may prove serious, especially the cardiac. The throat-condition may outlast the attack, and terminate in gangrene of the uvula or tonsils.

(2) *Henoch's Purpura*.—Henoch and Couty have described a form of rheumatic purpura occurring chiefly in children, and characterized by painful and sometimes swollen joints; by a purpuric eruption, plus erythema multiforme; by vomiting, diarrhea, and intestinal pain; by localized edema of the skin; and by hemorrhages from the mucous membranes and sometimes into the kidneys.

The *diagnosis* is difficult in proportion to the scanty development of the purpuric symptoms, some of which are often wanting. *Intussusception* usually occurs earlier—in babes.

The *prognosis* is favorable, though complications of more or less serious import may arise. One of Osler's cases proved fatal with the symptoms of acute hemorrhagic Bright's disease.

(3) *Factitious Purpura*.—Bruce and Galloway¹ report a case in which any irritation of the skin, such as might be caused by drawing the blunt end of a pencil over it, produced a white line, which presently became pink and then intensely purpuric. In this way letters, figures, and the like could be shown as hemorrhagic outlines.

(c) *Purpura Hæmorrhagica (Morbus Werlhofii)*.—This is the severest form of purpura, and its apparent etiologic connection with certain infectious diseases, particularly rheumatism, malaria, etc., is interesting, but

¹ *British Jour. of Dermatology*, Jan., 1898.

not well understood. The disease is perhaps most common in young females, particularly if they have fallen into general ill health; but all persons are liable, and post-mortem anatomo-pathologic pictures of the disease leave little room for doubt that it is an infectious complaint. Mayer¹ holds that the colon bacillus plays an etiologic rôle.

Symptoms.—*Prodromal symptoms*, (malaise, headache, depression, anorexia) may appear, and last one or two days. The invasion is moderately abrupt, with fever, and soon cutaneous ecchymoses appear upon the skin, quickly increasing in size and numbers. Slight hemorrhages from the mucous membranes into the internal organs occur. Epistaxis generally comes first; it tends to persist and to recur, and the same peculiarities pertain to bleedings from other points. *Prostration* now becomes rather marked, the patient complaining of pains in the limbs, loins, abdomen, and chest, and the latter often presage a fresh hemorrhage. There is moderate fever, as a rule, the temperature during the height of the attack ranging from 101° to 103° F. (38.3°–39.4° C.), or it may reach 104° to 105° F. (40.5° C.), though rarely. The pulse is accelerated (120 to 130 per minute), but full and regular, though in the worst cases it becomes small and very rapid. The mind is usually clear. The face may be pale and anxious. *Hematuria* followed by *nephritis* may occur.

There is secondary *anemia*, varying in intensity with the extent of the hemorrhage. It should be pointed out that the findings are more pronounced, owing to a greater loss of blood, in this form than in the preceding varieties of purpura. Occasionally the red count falls very low, while there is often a slight increase in the number of leukocytes, although the different varieties are present in normal proportions. "In stained specimens of purpuric blood the number of blood-platelets is found greatly diminished in severe cases" (Pratt). The course is run in from seven to ten days in mild cases, while the severer attacks pursue a longer course. The malignant form (*purpura fulminans*) has, however, a speedily fatal termination.

The *diagnosis* of purpura hæmorrhagica rarely presents any difficulty. *Scurvy* may simulate it in some particulars, but is distinguished by its chief etiologic factor—a diet deficient in fresh vegetables and fruits—by the spongy, swollen condition of the gums, the loosened teeth, and brawny induration of the limbs. Moreover, in purpura hæmorrhagica the hair-follicles do not occupy the centers of the ecchymotic spots, and the hemorrhages from the mucous membranes are more copious than in scurvy. Malignant types of the eruptive fevers distinguish themselves by the history of the prevailing epidemic, by the characteristic prodromes and invasion, and by the high temperature, although variola purpura often pursues an afebrile course. A blood examination, which should always be made in purpura, will exclude *leukemia*.

Prognosis.—Grave, except in mild cases. In the malignant type death may come before hemorrhages from the mucosa appear. Certain complications may prove fatal—cerebral hemorrhage, inundation of the lungs with blood, Bright's disease, and shock from rapid, profuse bleedings. Death may also be the result of exhaustion due to protracted bleedings.

Chronic Purpura.—Two forms have been described—one in which the stage of convalescence of the acute form is interrupted by recurrences

¹ *Medical Record*, March 26, 1909.

of the characteristic manifestations, the other in which the symptoms are continuous, lasting over months or years.

Treatment.—(a) The management of *secondary purpura* is embraced, in other portions of this volume, in connection with the treatment of the diseases and conditions which it accompanies.

(b) *Simple purpura* demands arsenic, first in moderate doses, and then increased until slight toxic effects are noticeable. Legroux speaks in warm terms of the iron compounds, and especially of iron perchlorid in doses of 3ss-j (2.0–4.0) daily, and if the child is somewhat anemic, the inhalation of oxygen will promote hematosiis. The disease also requires fresh air in abundance and a generous diet.

(c) *In peliosis rheumatica*, in addition to the measures recommended in *purpura simplex*, the salicylates should be tried.

(d) *Purpura Hæmorrhagica*.—In all kinds of *purpura* the patient should be confined to bed. An abundance of nourishment, by supporting the patient's power, is of the greatest service. Internally, ergot, turpentine, tincture of the chlorid of iron, acetate of lead, and dilute sulphuric acid enjoy the widest reputation. Calcium chlorid, suggested by Wright, should be tried, as should also adrenalin chloride. A 2 per cent. solution of gelatin in normal salt solution given subcutaneously is a remedy of great value. The following combination, recommended by Hardaway, I have found useful:

HEMOPHILIA.

(*Bleeder's Disease.*)

Definition.—An hereditary affection, transmitted by females who are themselves not affected (Nasse's law). It is characterized by frequent uncontrollable hemorrhages that are either spontaneous or due to slight traumatism.

Pathology.—The constitutional changes on which the disease depends are to be found in the blood-vessels rather than in the blood itself (Henry); microscopic changes have been found in the arterioles, the middle muscular tunic being either absent or much atrophied. Vasomotor influences also play an important part in causing an attack. The blood presents slight changes, although Addis holds that the cause of hemophilia is an inherited peculiarity in the constitution of the prothrombin whereby its activation into thrombin is retarded. Synovitis with hemorrhages into the joints may sometimes be observed.

Etiology.—Hemophilia is more distinctly hereditary than any other known disease, but Nasse's law is not of such universal application as is supposed. R. Kolster found that of 50 hemophilic families, 18 cases followed this law, 16 others with some exceptions to its provisions, and 12 without any regard to it. The law embraces the following points: The daughter (not herself affected) of a bleeder transmits the tendency to her sons, who become bleeders; her daughters do not suffer, but in

turn transmit the disease to their sons. Females, however, may be bleeders, and, according to Virchow, one woman is affected to every seven men. The disease has been traced for centuries in a few families.

It is observed in all classes of society, and is most frequent in families whose members are large, vigorous, and have delicate complexions, the complaint usually manifesting itself before the end of the second year of life, though exceptionally as late as puberty. An acquired hemorrhagic diathesis is seen occasionally in connection with certain acute infections and more commonly in the graver anemias (leukemia, pernicious anemia).

Symptoms.—The occurrence of profuse and persistent bleedings that are either spontaneous or the result of slight injury characterizes hemophilia. The character of the injuries that lead to dangerous bleedings is often exceedingly trivial; thus a slight scratch, cut, blow, the extraction of a tooth, and other minor surgical operations (*e. g.* circumcision) may be followed by severe hemorrhage.

If we include spontaneous hemorrhages, bleedings take place most frequently from the nose. Legg has made three clinical groups, based on the intensity of the symptoms, as follows: (1) Seen most frequently in men, and characterized by external and internal bleedings of all kinds and by joint-affections; (2) most frequent in women, and distinguished by spontaneous hemorrhages from mucous membranes only; and (3) characterized simply by ecchymoses.

The capillaries ooze blood—a process that may vary in duration from a few hours to as many weeks. A fatal result may occur in a few hours, while, on the other hand, recovery may follow a slow oozing of blood that has continued for many days. In the latter instances profound anemia follows, the blood, however, being rapidly replaced. Extensive blood-extravasations (hematomata) usually follow contusions. Petechiæ, when they occur, are apt to be spontaneous. The coagulation time of the blood is delayed, due to insufficient formation of the fibrin ferment factors (Morowitz and Lossen). Fussell, in 2 cases, found the leukocytes increased (24,000 and 15,000 per c.mm.), while the red cells were moderately diminished.

Arthritic symptoms are common, the larger joints, and especially the knees, being most frequently affected and showing swelling that is due chiefly to hemorrhages into the joints. In other instances febrile synovitis may be present, resembling rheumatism. The joint-symptoms may either announce an approaching hemorrhage or pain alone may be experienced. The attacks are liable to recur, especially in cold, damp weather, and may result in stiffened, deformed joints (Musser).

Diagnosis.—When persistent capillary oozing occurs in a person with a clear, hereditary disposition the diagnosis is clear. Without an inherited tendency we cannot be certain of the diagnosis unless protracted hemorrhages from insufficient causes are repeatedly manifested. The presence of joint-involvement is very helpful.

Differential Diagnosis.—*Peliosis rheumatica* is an affection which, as Osler remarks, touches hemophilia very closely, particularly in the relation of the joint-swelling. It is true that the former may also show itself in several members of a family, but the presence in this affection of more or less edema, and often of wheals of urticaria, accompanied by intense itching, aids greatly in its elimination.

Prognosis.—In undeveloped forms the outlook is not particularly

grave, since in these the tendency may either lessen or become altogether arrested after childhood. In the majority of well-marked cases the children do not survive this period. On the other hand, those who live to become full-grown show a diminished, and in a small class of cases an absolute, disappearance of the tendency. The first hemorrhage rarely proves fatal. Boys suffer from a more serious form than girls. Moreover, menstruation, though sometimes very copious, does not to any great extent endanger the life of a hemophilic woman. Of 130 cases of pregnancy and labor, the death of the mother occurred in only 3, and abortion in 16 cases (Kolster).

Treatment.—The physician can do most in the direction of prophylaxis. All surgical operations that are not absolutely necessary must be avoided; neither should the teeth be erupted nor the operation of circumcision be permitted. Leeches are not permissible. Females who belong to bleeder families, as well as males who have had hemophilia, should not marry.

During the attack absolute rest—mental and bodily—must be enjoined, and light compression, and if this fail strong pressure or styptics, should be tried. In epistaxis ice, tannin, and turpentine should be tried before using nasal plugs; and if the latter prove indispensable, the lightest only should be employed. J. Greig Smith regards lint saturated with spirit of turpentine as the best local application in epistaxis. Adrenalin chloride and gelatin in 5 per cent. solution are of great value locally. Internal medicines are of secondary importance, but opium is unquestionably of value, since it tends to favor repose. The remedies that have been given are various. Delafield, Fürth, and others have used successfully the fluidextract of *hydrastis canadensis*, the dose being from 20 to 40 drops daily; among other hemostatics, gallic acid, turpentine, and iron perchlorid produce the best results. The dose of the latter should be 3ss (2.0) every two hours, with a purge of sulphate of soda (Legg). The use of calcium salts has produced good results in some cases and merits a trial, as does adrenalin chloride. The subcutaneous injection of the gelatin solution already mentioned has undoubted value. Gelatin seems also to have hemostatic power when given by mouth or rectum. The most successful method (first advocated by Weil) is fresh normal blood, either from the horse, or rabbit, or human blood (Lappe). The dose of the fresh serum if given subcutaneously is 20 to 40 c.c. The coagulability of the blood is greatly increased thereby. Sahli advises repeated injections of fresh human serum and repeated small bleedings to stimulate the physiological reactive thrombokinas formation. Thyroid extract and inhalations of oxygen have also been advocated. During convalescence, arsenic, iron, the bitter tonics, and a liberal dietary will aid full recovery.

HEMORRHAGIC DISEASES OF THE NEW-BORN.

(a) **Epidemic Hemoglobinuria** (*Winckel's Disease*).—This affection, which is *septic* in nature, is occasionally met with in lying-in hospitals, and occurs in children from one to ten days after birth. The infants refuse the breast and show hematogenous (?) icterus; gastro-enteric

catarrh is an attendant of the disease. The stools are meconic; the urine is scanty, dark colored (from methemoglobin), often albuminous, and may contain casts. Hemorrhages occur into organs other than the kidney and into the mucous membranes, there also being mild fever, rapid emaciation, and often mild convulsions. It is a very fatal disease. Bacteriologic experiments have shown that the disease may be produced by the growth of the colon bacillus in the buccal epithelium of infants. Kilham and Mercelis¹ report an epidemic of 10 cases occurring in the New York Infirmary; complete bacteriologic studies were made in all, and the organism discovered suggested the diplococcus of pneumonia or the pneumococcus group. There is, however, great confusion in regard to the possible specific micro-organism of this disease.

(b) **Acute Fatty Degeneration of the New-born (*Buhl's Disease*).**—This disease may be similar to Winckel's in nature. It was first described by Hecker and Buhl as an infectious disease of the new-born, characterized by cyanosis, jaundice, and copious visceral hemorrhages. The chief *pathologic change* is an acute fatty degeneration of the internal organs.

(c) **Syphilis Hæmorrhagica Neonatorum.**—Either at birth or soon thereafter bleedings take place into the skin (ecchymoses) and from the mucous surfaces and the navel. Jaundice may be associated. The viscera are found upon post-mortem examination to be the seat of syphilitic lesions.

(d) **Morbus Maculosus Neonatorum.**—Hemorrhage from the gastrointestinal mucosa of the new-born (*melæna neonatorum*) occurs, and may be due to intracranial lesions during birth; it may also take place independently of the latter. Preuschen has collected the reports of 37 cases, in 5 of which the brain was examined, and all of these showed cerebral hemorrhages. The latter may occur in spontaneous births and give rise to *melæna neonatorum*. Gärtner believes the disease to be an infectious one, and claims that in 2 cases he was able to identify a bacillus for which the navel is believed to be the entrance-point. The blood may also come from the mouth, nose, navel, etc. Townsend found *morbus maculosus neonatorum* in 45 cases in 6700 deliveries, and in most of these instances the bleeding was general. The hemorrhage usually sets in during the first week, rarely later, and the duration of the disease is between one and seven days, the mortality being a little over 50 per cent. Vomiting of the blood which the child has drawn from the breast must not be confounded with true *melæna*. The *treatment* is by gallic acid and ergotin, the latter hypodermically. Gelatin subcutaneously has apparently saved life.² Stimulants may also be required, and warmth to the extremities if the peripheral circulation be sluggish.

PART IV.

DISEASES OF THE BLOOD AND THE DUCTLESS GLANDS.

ANEMIA.

Definition.—A pathologic condition, characterized either by a diminution in the quantity of blood or by a deficiency in one or more of its constituents. Anemias may be subdivided into—I. Primary or Essential (simple, chlorotic, and pernicious); II. Secondary (symptomatic); III. Leukemia (splenic, myelogenic, and lymphatic).

Pathology.—Anemia, in its different forms, is characteristic of diseases of the blood or of the blood-making organs. It may be manifest, on examination, as a diminution of the total quantity or body of the blood (*oligemia*); of the number of red corpuscles (*oligocythemia*); of the hemoglobin (*oligochromemia*); and of other constituents, as fluid (*anhydremia*). The diminution of hemoglobin gives rise to the most obvious sign of anemia or impoverished blood—namely, the pallor of the cutaneous surface—but it is important to point out here that the quantity of hemoglobin in the blood is not necessarily proportionate to the number of red corpuscles. Thus the percentage of hemoglobin contained by the red corpuscles may vary in disease, so that a reduction in its amount does not necessarily involve a corresponding decrease in the number of red corpuscles. Conversely, a diminution in the number of the latter may not be accompanied by a proportionate diminution in the amount of hemoglobin, the corpuscular richness in coloring-matter being quite normal. As a matter of fact it frequently happens that oligochromemia is associated with a certain degree of oligocythemia, and *vice versa*, though where they coexist the degrees of reduction may neither be relatively nor proportionately equal.

Anemia can be positively ascertained only by an adequate examination of the blood. It may be inferred from the presence of pallor, languor, dyspnea, palpitation, etc.; but it should be borne in mind that not every pale person has anemia, since pallor of the face may be hereditary, and, at the same time, perfectly consistent with good health, a normal number of corpuscles, and a normal percentage of hemoglobin. Conversely, a person with marked vascularity of the face, and a rosy complexion even, may have anemia.

The anemias embrace those conditions, also, in which there are changes in the shape of the red corpuscles (*poikilocytosis*), and in their size (*micro-, macro-, or megalocytosis*).

I. THE PRIMARY OR ESSENTIAL ANEMIAS.

Primary anemias constitute those forms in which, so far as our present knowledge of their etiology and pathology goes, no other tissues or organs than the blood and the blood-making organs are either at fault or are directly affected. Future investigations of the life-history of the blood may reveal the exact causation of what are now regarded as primary or essential anemias, and thus permit of a clearer discrimination and a more accurate classification.

SIMPLE OR BENIGN ANEMIA.

This form is not infrequently met with as a congenital, constitutional affection, without any assignable cause, and is entirely free from pernicious manifestations or tendencies. There is no discoverable element of relationship between simple benign anemia and chlorosis.

Etiology.—Simple constitutional anemia is often met with among the poorer classes, and from this fact it is probable that living or working in a vitiated atmosphere, as well as deficient sunlight and nutriment, is primarily active in reducing the general health. There are also certain individuals in whom slight pallor and systemic feebleness have existed from infancy (thus probably congenital), and whose modes of life and environment have been more or less uniformly hygienic and provident.

Symptoms.—There is pallor, often with languor, slight palpitation, and dyspnea, occasional headache, and a tendency to fatigue. The general health is not otherwise disturbed, and an active life may be enjoyed for many years. Examination of the blood shows a slight reduction in the number of the red cells and of the hemoglobin (relative). This degree of anemia persists without aggravation or amelioration.

The **diagnosis** of simple, benign, or constitutional anemia should be made with considerable caution and reserve. If there be a latent or incipient tuberculosis, carcinoma, or nephritis, a previous attack of some infectious fever, rheumatism, etc., this fact clearly bears upon the case, and the diagnosis of simple anemia is precluded.

The **prognosis** is usually favorable.

The **treatment** of simple, benign anemia is an expectant one in most instances. Hematinics (iron, arsenic etc.) are seldom required, as they have little if any influence upon the blood or upon the pallor or other symptoms. A rigid system of hygiene, together with attention to proper food and drink and to the manner of eating and drinking, will ensure to the patient all the benefit that may be obtained. Cardiac tonics (digitalis), may be useful in controlling the palpitation.

CHLOROSIS.

(*Green Sickness.*)

Definition.—A blood-disease, occurring chiefly in adolescent females, dependent upon defective hemogenesis, and characterized principally by a deficiency of hemoglobin in the red corpuscles. Chlorosis is steadily diminishing in frequency of occurrence.

Pathology.—It is so seldom that death occurs in cases of chlorosis

that autopsies of this disease have not been frequent enough to determine definitely the nature of the findings. There is no loss of fat in the body, but signs of physical degeneration and disorders of development are quite common, hypoplasia of the vascular system and of the genital organs seeming to be the most prominent. Incurable cases of chlorosis are nearly always characterized by anomalies of the blood-vessels and genitalia (Rokitansky). Virchow has also shown that congenital arrest of development of the aorta and larger arteries, as indicated by their small size, their soft and elastic walls, is quite constant in chlorotics. The uterus (especially) and adnexa manifest the hypoplasia, and yellowish spots and streaks of fatty degeneration are sometimes seen in the intima of the arteries. The cardiac muscle is softened, the whole heart is dilated, and the left ventricle is usually somewhat hypertrophied.

Etiology.—Chlorosis occurs most frequently in girls at or near puberty, and also may appear between that period and twenty or twenty-five years of age. It usually happens that the condition dates from a scanty menstruation, beginning late in the “teens,” but it should be recollected that amenorrhea is not, as formerly supposed, a cause, being rather an effect of the underlying blood-disorder. Blondes are oftener affected than brunettes. In males the disease is rare, though cases may develop at puberty or during adolescence.

The influence of *heredity* in the causation of chlorosis is undoubted in those cases described by Virchow, in which congenital hypoplasia of the blood-vessels and genitalia is found to exist. Other cases also bear the stamp of heredity, in that their mothers have been, and their sisters are, chlorotic. A *family tuberculous taint* may predispose to chlorosis (Jolly); it is probable, however, that constitutional predisposition implies merely delicacy of organization. Such *unhygienic conditions* as bad air, dimly lighted rooms, a lack of nutritious food and out-door exercise, a sedentary occupation, hasty and irregular eating, excessive tea- and coffee-drinking; bodily fatigue, as from stair-climbing and standing in constrained positions without intervals of rest—all these predispose to the disease. And yet girls living amid the most luxurious and favorable surroundings have had chlorosis. Sir Andrew Clarke believed that *copremia*—the absorption of the toxic ptomains and leukomains from the colon in constipation—is often the cause of chlorosis, though physiologic chemists fail to find in the urine the evidences of intestinal putrefaction. Sometimes a previously existing simple constitutional anemia appears to be an underlying cause for an exacerbation of genuine chlorosis. I believe that occult gastro-intestinal bleeding due to gastric or duodenal ulcer may be a cause of chlorosis.

Sudden emotional excitement and prolonged mental overexertion operate as causative agencies. Shock from bad news, such as loss of relatives, homesickness, disappointment in love, rankling grievances, and perhaps ungratified sexual desires, may contribute to the “neuro-pathic” origin of chlorosis. A change of climate seems to operate as a cause, and is manifested especially in the case of girls emigrating from rural Ireland to enter domestic service here (Townsend). A *late chlorosis* has also been described, but its existence must be rare.

Symptoms.—A brief outline of the more frequent and prominent general manifestations of chlorosis—or “green sickness”—may be nar-

rated at the outset. The gradual onset is usually marked by languor, indisposition to either physical or mental exertion, motor weakness, irritability or inertia of mind, depression of energy, and a more or less constant fatigue. *Palpitation of the heart* and *dyspnea* on slight exertion are much complained of in most cases; *headache* is also an early symptom, and may be accompanied by vertigo in some cases; and *dyspepsia* and *constipation* occur in 65 per cent. of cases (Townsend). Probably in one-half of all cases cessation of, or scanty and irregular, menses may form the burden of complaint. A slight fever is present in many instances.

Gastro-intestinal Symptoms.—The appetite is either poor or perverted and a capricious desire for such innutritious substances as chalk, slate-pencils, and even bits of earth (*pica*), or for sour, highly spiced, and unwholesome articles of food (*malacia*), is not uncommon. An abnormal craving for alkalies has been ascribed to an overacid stomach. Morning vomiting or regurgitation of food and eructations occur, in some cases pain after eating may be noticed, and dilatation of the stomach and high position of the diaphragm are found in many instances. The gastric contents show a hyperacidity in most cases. The tongue is pale, flabby, often dry, and the edges show indentations.

Constipation is usually present, though sometimes *diarrhea*, lasting for a day or two, may alternate, as after the ingestion of some unwholesome article that has been eaten to satisfy the perverted appetite.

General Appearance.—The subcutaneous fat is not only well retained, but in many cases is even increased, and the rotundity of the body and members preserved. The peculiar *greenish-yellow tint* of the complexion is, however, the most striking manifestation to the eye. It differs thus from the muddy pallor of cancerous anemia, from the lemon-yellow tint of pernicious anemia, from the saffron hue of jaundice, and from the blanched pallor after severe hemorrhages. The *scleræ* are often pearly- or bluish-white ("cerulean hue"), and, though this is considered by many the earliest positive indication of anemia, when the skin-tint is not characteristic. yet, according to Townsend's analysis of 87 cases of chlorosis, it is not the most constant. The *nails* showed pallor in 95 per cent. of the cases; the cheeks, tongue, and lips were pale in 89, 84, and 76 per cent. respectively, while the *scleræ* were pale in but 64 per cent. On exertion the cheeks and lips may become quite ruddy in cases of moderate anemia (*chlorosis rubra*).

Circulatory symptoms are breathlessness, palpitation, and the tendency to vertigo and syncope complained of in the majority of cases; other circulatory disturbances may occur. The *skin* and the extremities are frequently cold, owing to sluggish heart-action. The *pulse* is usually full and easily compressible, and, owing to its excitability, it may be accelerated for the time being by various external influences (see Fig. 34). Visible undulating pulsations of the carotid vessels are frequent, and a pulsation at the base of the heart and in the peripheral veins is also observed at times. Physical examination shows the *heart* to be slightly dilated. Systolic murmurs, soft and "whiffing" in character, are heard at the base, though in severe cases they may be heard at the apex of the heart also. *Systolic blowing murmurs* of hemic origin are not infrequently heard over the carotid arteries. More common and

characteristic, however, is the *venous hum* or *bruit de diable*—the soft continuous murmur heard over the large cervical veins. Thrombosis of the larger veins or of a cranial sinus may occur, and is always ominous.

Of the *nervous manifestations* that are often present, neuralgias of the head, mental depression, hyperesthesia of the skin, particularly of the abdomen, gastralgic attacks, and hysteria, are most frequently met with. Tinnitus aurium and anemic amaurosis have been known to occur.

Edema of the ankles is found in perhaps one-third of the cases. The *urine* is generally pale, free in quantity, and its specific gravity is somewhat lowered; and according to recent studies there is a diminished

FIG. 34.—Pulse- and temperature-chart of a case of chlorosis, showing the effect exerted upon the pulse by eating, exertion, and excitement.

excretion of urea, despite the abnormal destruction of albuminoids. Movable kidney is often associated.

Blood-examination.—The blood flowing from a punctured finger-pulp or ear-lobule is pale, though seldom thin or hydremic, and the paleness is due to a qualitative rather than a quantitative change. There is a disproportionate reduction of the *hemoglobin* as compared with the number of the red cells. The hemoglobin may range from 50 per cent. to as low as 16 or 17 per cent. in severe cases, the average quantity being about 38 or 40 per cent. On the other hand, the number of red corpuscles is not greatly reduced, and may even be normal. The moderate *oligocythemia* and *marked oligochromemia* are almost distinctive of chlorosis: these features, however, may be closely simulated by the chloroanemia of syphilis or early tuberculosis. Morawitz¹ calls attention to "masked chlorosis," in which Seiler found that the hemoglobin percentage was only 10 or 15 below normal. The average number of red corpuscles is from 3,700,000 to 4,100,000 per cubic millimeter of blood, but the count in very severe cases may be as low as 1,900,000. Approximately, the number of red corpuscles is from 70 to 85 per cent. of the normal, while the leukocytes are only slightly increased in number (8000 to 8500 per c.mm.). *Microscopically*, the red cells are seen

¹ *Münchener medizinische Wöchenschrift*, July 5, 1910.

to be paler than normal, and somewhat altered in size and shape. Some are distinctively larger than is usual (macrocytes), but the majority are slightly undersized (microcytes). Irregularity in shape (poikilocytosis) is seen in quite a number of the red cells in the severe cases, and an occasional normoblast (small nucleated red corpuscle) may be noted. There is usually a relative lymphocytosis, especially in severe cases. The eosinophiles are occasionally increased (Cabot). There is a marked increase in the amount of blood plasma (polyplasmia).

Diagnosis.—When the greenish pallor of the face is marked this can often be correctly made at a glance. The blood-examination must be made, however, to completely establish the diagnosis, even when distinctive symptoms are present, such as the shortness of breath, palpitation, weakness and languor, faintness, amenorrhea, capricious appetite, together with a well-nourished appearance of the body. The bluish-white scleræ and pallid nails are confirmatory when observed, and search should be made for the physical signs.

Differential Diagnosis.—The primary character of the anemia may be determined in doubtful cases, or in those in which *incipient tuberculosis* ("chloro-anemia"), or *syphilis*, or *Bright's disease* may be suspected, by exclusion. Here the physical examination of the chest, the history, and urinalysis should supplement the blood-examination. In the chloro-anemia of chronic phthisis fever and progressive emaciation are also observed. *Organic disease of the heart* may be simulated by the breathlessness, palpitation, vertigo, and edema.

Prognosis.—This is always favorable, except in those cases in which congenital or developmental anomalies of the vascular system are associated. The discontinuance of proper treatment before a substantial cure is effected is often followed by a relapse, and even after apparent cure one or more recurrences may be witnessed before the age of thirty. The average duration of a case of chlorosis is from two to three months. In cases of very severe type, in which the dividing-line between this disease and pernicious anemia may not be marked clearly, the prognosis should be made with due reserve.

Treatment.—While the treatment of chlorosis by the administration of iron is wellnigh specific, the *hygienic measures* are also important, and particularly in order that relapses may be avoided.

Hygienic.—Pure air, wholesome food, and plenty of rest and sleep, with regular habits, are prime requisites. Sometimes a change of occupation, even temporary, where confinement may be replaced by an outdoor life and sunshine, as in the case of store-girls and mill-operatives, is of value in bringing about a rapid improvement. Patients in better circumstances may be sent to rural districts, the mountains, or sea-shore. In cases marked by much palpitation, dizziness, and dyspnea, rest in bed for a week or so is often imperative at the outset. As improvement goes on, however, light and then moderate exercise may be permitted, and the increasing appetite should be gratified by a generous, easily assimilable diet (milk, meat, eggs, fish, purées of green vegetables, stewed fruit). Fats and carbohydrates should generally be avoided. Coffee, tea, and alcoholics do harm. Hot baths have been recommended.

Medicinal.—The one remedy, *par excellence*, on both rational and empirical grounds, is a good preparation of *iron*. This should be given methodically and persistently until the percentage of hemo-

globin is 90, and then maintained there by continuing the administration of the iron for several weeks to prevent a recurrence (Fig. 35). Exactly how the iron acts in curing chlorosis has not been definitely proved, but its almost specific action is indubitable. Not all preparations of iron are equally well borne by the stomach, however, and sev-

FIG. 35.—Chart of a case of chlorosis, showing the improvement following the administration of iron. Convalescence almost complete; relapse. Black, red corpuscles; red, hemoglobin; blue, white corpuscles.

eral changes may be necessary during the course of a given case. Probably the best form for general use is the dried sulphate, usually given together with potassium carbonate in the well-known Bland's pills—2 grains (0.129) of each to the pill. Starting with one pill thrice daily for a week or ten days, the daily dosage is increased until nine pills daily are administered in the third week, and continued for several weeks or as long as the case may require. It is very important, meanwhile, that the bowels should be kept soluble by the use of cascara sagrada, salines, and the like. A preliminary course of intestinal antiseptics for a week or so is strongly advised by some authorities, and is worthy of recommendation. Beta-naphthol, thymol, guaiacol, and salol are used for this purpose. The hematinic effect of the iron seems to be produced earlier and better when this plan is followed; and this fact seems to give corroborative evidence to Bunge's theory of the absorption of the iron in chlorosis—in a certain class of cases at least. Other iron preparations of value in this disease are the citrate, protoxalate, lactate, carbonate, the succinate, and the reduced iron. The albuminates of iron, so much

vaunted for a time, are practically worthless. In severe cases Quinke uses at first a 5 per cent. solution of the ferric citrate hypodermically (m viiss-zuiss —0.5–10.0, daily). Bitter tonics and dilute hydrochloric acid are indicated in a certain number of cases in which indigestion is troublesome. The acid tincture of iron chlorid is sometimes used in such cases. Mild cases often yield to the simple use of remedies for the cure of gastro-intestinal derangement. Adjuvants in the treatment of chlorosis that may be of use are arsenic, manganese, mercuric chlorid, and arsenite of copper in minute doses. Kottman thinks that rarely venesection is required in obstinate cases to whip up the torpid blood-producing apparatus.

PROGRESSIVE PERNICIOUS ANEMIA.

(*Idiopathic Anemia* ; *Biermier's Anemia*.)

Definition.—A grave blood-disease characterized by a great destruction of red corpuscles, and a persistent tendency from a bad to a worse condition. It usually ends in death, and seldom exhibits causal lesions other than those of the blood or blood-making organs.

The term “idiopathic anemia” applied to this disease by Addison, whose first clear description of its clinical history has become classical, is applicable to a proportionately smaller number of cases to-day than during his time. This is owing to the later discovery (*post-mortem*) of adequate causes for the pernicious anemia that during life could not be found. Thus, while Biermier’s anemia is usually considered a special disease-entity, for descriptive purposes it will be convenient to classify both groups under the title of *progressive pernicious anemia* in order to describe the invariable tendency of both. Under Diagnosis (*vide infra*), however, will be found differential clinical features.

Pathology.—The subcutaneous fat is rarely diminished, so that emaciation is exceptional. The skin is pale and of a lemon-yellow tint, and most of the tissues and organs are anemic, except the muscles, which are often decidedly red in color. The fat is usually pale and yellowish, and fatty degeneration is one of the most striking changes in this affection. The heart is usually large and flabby, and on section of the ventricular walls there is a marked pallor, as well as a friability, and a fatty change shown by the yellow tint. Microscopically, the fibers or columns of heart-muscle are seen to be distinctly fatty. The heart-cavities contain little light-colored blood. Other organs showing the fatty degeneration (of the epithelium) are the liver, kidneys, gastric and intestinal walls, and the intima of many of the smaller blood-vessels (in patches). This general fatty change is probably due to the deficient oxygenation of the tissues and to the anemic blood-supply.

Owing to the above degenerative change in the vessel-walls, small extravasations of blood are found in different parts. Most frequently these punctiform hemorrhages are seen in the retina and on the principal serous membranes. Ecchymoses are also observed occasionally on the mucous membranes and on the skin. More or less general edema and dropsical accumulations in the serous cavities are not uncommon. The spleen and liver are seldom and only slightly enlarged. The lymph-

glands are often somewhat swollen and intensely red in color, owing to the unusual number of red corpuscles.

In a series of 8 cases, Warthin¹ has found changes in the hemolymph glands consisting of "dilatation of the blood-sinuses and evidences of increased hemolysis, as shown by the increased number of phagocytes containing disintegrating red cells and blood pigment."

A marked and important pathologic feature of pernicious anemia is the presence of abundant deposits of iron-pigment, especially in the liver, but also in the spleen, kidneys, pancreas, and other organs. The fact that the abnormal quantity of iron in the liver is peculiarly distributed about the periphery and middle zone of the lobules is particularly noteworthy, and quite characteristic of pernicious anemia. The origin of this iron is doubtless the enormous destruction of red corpuscles, and that the pigment in the hepatic lobules is ferruginous may be determined by a micro-chemic test with ammonium sulphid, granules of black sulphid of iron being formed.

Of special interest are the lesions found in the bone-marrow on account of its hematopoietic function. This is virtually hypertrophied, and is in many cases deep-red instead of yellow, and more like the hemoblastic marrow of childhood (H. C. Wood). While formerly held to be causative, this change is now regarded as being secondary to the severe anemia. Cellular hyperplasia may be seen microscopically in the great number of large and small granular medullary cells, and also in the nucleated red cells.

An atrophied condition of the gastric and duodenal mucosa is noticed in some cases. The sympathetic ganglion cells may also show changes. More constant, however, is the sclerosis of the posterior columns and, to some extent, of the lateral columns of the spinal cord: this is especially marked, according to Burr, in the cervical swelling. Patveu examined 9 cases; in 4 he found hyaline degeneration of the vessels of the white substance, and in 5 small hemorrhages. These changes are probably due to a toxic agent.

Etiology.—There are three etiologic categories into which cases of pernicious anemia may be grouped: (1) those cases in which no discoverable cause for the hemolysis (blood-destruction) is ascertained, either during life or after death—*i. e.* the idiopathic variety of Addison; (2) those in which an adequate cause is found *post-mortem* only; (3) those that are apparently traceable, *ante mortem*, to some primary causal condition acting directly or indirectly.

(1) As regards the *obscure (genuine) cases* of idiopathic anemia, the essential cause of the symptomatic condition is evidently an actively increased *hemolysis*. The blood-generation (hemogenesis) may be normal in power, or there may be a congenital or acquired underlying deficiency in hemogenic power. Grawitz and Stengel believe that the hemolysis originates in the gastro-intestinal capillaries and depends upon poisons generated or absorbed from that tract—an auto-intoxication. Von Jaksch holds that the similarity of pernicious anemia to Kala-azar suggests a protozoon infection. William Hunter² concludes

¹ *Amer. Jour. Med. Sciences*, October, 1902.

² *Lancet*, January 27, 1900.

that the disease is of infectious (streptococcal) nature, dependent primarily upon caries of the teeth. Goullard and Goodall¹ hold that a hemolytic toxin (not necessarily its primary seat in the intestines) acts on the bone-marrow.

(2) Apparently causeless cases of a pernicious type of anemia may be found *post-mortem* to have been caused by (a) obscure malignant disease; (b) parasites, especially the *Ancylostoma duodenalis*, and rarely by the *Bothriocephalus*. Not infrequently, by a careful study of the anamnesis of a patient, aided by modern methods of examination, the cause of pernicious anemia may be detected during life. It is held that atrophy of ventricular and intestinal glands is an effect rather than the cause, as formerly believed of the anemia (Grawitz).

(3) Certain exhausting causes, operating directly or indirectly, may precede this affection, as severe or prolonged hemorrhages or diarrhea, fevers, mental shock, profound chlorosis, pregnancy, and parturition.

Predisposing Causes.—Unfavorable hygienic surroundings and insufficient nourishment, habitually kept up, may also favor the development of the disease. Males are more frequently affected than females after the thirty-fifth year and it occurs mostly during middle life. Griffith has collected several cases occurring under twelve years of age. The disease is widely distributed, and it may behave endemically at times, as in Switzerland and Leipsic. Changes left in the tissues (bones?) after syphilis may be the pathologic basis, and osteosarcoma may act similarly.

Symptoms.—Idiopathic pernicious anemia develops so slowly and insidiously that it is hardly ever possible to fix upon any precise date as the commencement of the disease. The transition from health to progressive pernicious anemia, particularly in persons previously feeble and pale, is usually too gradual to be demonstrable; though a rapid and acute onset is rare, it may occur in pregnant or puerperal women.

Pallor is soon noticed and gradually increases, or when there has been a previous pallor, this becomes more marked. *Shortness of breath* and *palpitation of the heart*, especially on exertion, are complained of; the patient is also easily fatigued, and becomes quite languid. Occasional nausea may come on early in those cases in which a previous gastro-intestinal disturbance has been noted, and headache, vertigo, tinnitus aurium, and anorexia ensue and grow progressively worse. General weakness increases, and occasional attacks of faintness and vomiting supervene. Meanwhile, the skin takes on a bloodless, waxy appearance, and soon the characteristic *lemon-yellow tint* appears. The mucous membranes are pale and colorless. *Prostration in bed* gradually becomes almost absolute as the feebleness and flabbiness of the tissue increase. *Malleolar edema* is sometimes noticeable, and ecchymoses—mucous and cutaneous—are seen in profound cases of anemia. Although the intellect is not impaired, except that mental exertion becomes irksome, the tone and manner of speech are feeble. As the debility becomes severe the mind wanders, and, to use Addison's words, the patient "falls into a prostrate and half-torpid state, and at length expires."

¹ *Jour. Path. and Bact.*, January, 1905.

Emaciation is rare, the fat being preserved and sometimes increased in quantity. Pulsation in the large arteries is abnormally visible, and a diffuse, exaggerated cardiac impulse is felt. The *pulse* early in the case may be strong, and generally it is rapid (100–120), soft, and compressible, and as full and quick, often, as the water-hammer pulse of aortic regurgitation. Auscultation reveals the constant and characteristic *hemic murmurs*, best heard at the base, and the *bruit de diable* in the veins of the neck. There may be visible pulsations in the latter.

Gastro-intestinal symptoms may be the most prominent signs where gastritis polyposa and gastritis atrophica are present. Diarrhea, dyspepsia, nausea, and vomiting are then seen throughout the course; otherwise, constipation, eructations, and simple anorexia are most common.

An ophthalmoscopic examination shows the cause of the *anemic amaurosis*, in the profound cases of anemia, to be one or more retinal hemorrhages. The whites of the eyes become pearly, the conjunctivæ pale. The liver and spleen are rarely palpable. The bones, and especially the sternum, are sometimes sensitive to pressure.

Respiratory Symptoms.—The breathing is accelerated, and the *anemic dyspnea* may become pronounced and stertorous, accompanied by a sense of thoracic oppression and a “hunger for air.” Near the end pleural and pericardial serous effusions and pulmonary edema may appear.

The *urine* is of low specific gravity, and, on account of its pigmentation with pathologic urobilin, dark in color. The urobilin is detected both by chemic and spectroscopic examination. In the former the addition of a few drops of an alcoholic solution of zinc chlorid to the urine gives a green fluorescence. The presence of *indican* in the urine points to albuminous decomposition in the intestines. Albumin and glucose are absent, but uric acid and urea are both increased in amount, the former occasionally and the latter usually.

Fever of a moderate degree is commonly, though not invariably, present, the evening temperature sometimes reaching 102° F. (38.8° C.). Previous to death the temperature may be subnormal.

Nervous Symptoms.—Paresthesia, spastic paralysis of the limbs, and a loss of control of the sphincters indicate the paralytic tendency of those cases in which sclerosis of the cord occurs. Tabetic symptoms are sometimes marked.

Blood-examination.—The blood is usually pale, though sometimes dark and watery, and the oligocythemia is distinctive of pernicious anemia. The number of red corpuscles may be reduced to less than 200,000 per c.mm., and is seldom more than 1,000,000. The percentage of hemoglobin may be approximately proportionate to the number of red corpuscles in the earlier stages, but as the disease progresses the index rises, so that the individual corpuscles are rich in hemoglobin. In other words, although there is a reduction in the total amount of hemoglobin, it is usually not so great as the reduction in the number of erythrocytes; therefore, the color index is nearly always relatively higher than that of the red globules (see Fig. 36), a condition in marked contrast with chlorosis. Macrocytes (which cause the relatively higher percentage of

hemoglobin), microcytes, poikilocytes, and polychromatophilia are constantly present, and the former abundant. The presence of nucleated red corpuscles is also a striking characteristic of pernicious anemia. When normal in size they are known as *normoblasts*; when very large, as *megaloblasts*. In the former, according to Ehrlich, the eccentrically placed nuclei stain deeply; in the latter the large nuclei stain faintly. The former are typical of those nucleated red globules found in the hematopoietic organ of adults; the latter of those found in the blood-development of embryonic life. Megaloblasts may be found in non-idiopathic anemias. There are other forms of degeneration of the red

FIG 36.—Blood-chart of a case of progressive pernicious anemia. Black, red corpuscles; red, hemoglobin.

cells, and Grawitz regards the microcytes of importance as showing erythrocytic degeneration. There is usually a relative increase in the small lymphocytes at the expense of the polynuclear cells; and, according to Cabot, there was always a marked leukopena in a series of 110 cases.¹ Myelocytes are almost constantly present, though usually in low percentage. The average is about 2 per cent. The blood-plates are generally fewer than normal. The blood-plasma is markedly decreased (Adami). Cabot² found that a blood examination made for the first time during the period of remission may resemble that in chlorosis, and in 9 of 14 cases ring-like bodies were seen in the red cells.

Diagnosis and Differential Diagnosis.—The clinical characteristics of the affection, particularly their steady progression with remissions, are quite as important as microscopic study of the blood. An important blood feature of the disease is a high color index. The possibility of hidden carcinoma, gastric atrophy, the anchylostoma or other parasite, and incipient tuberculosis should be borne in mind also. *Intestinal parasites* are recognized from the microscopical examination of the feces after a brisk purge when the eggs of the parasites or the parasites themselves may be found. *Atrophic gastritis* may be discriminated by examining the viscus and gastric juice by modern methods. The following table will permit the elimination of obscure gastric carcinoma as a rule:

¹ Cabot, *Medical News*, May 5, 1900. ² *Amer. Jour. Med. Sciences*, Aug., 1900.

PROGRESSIVE PERNICIOUS ANEMIA.

The blood shows characteristic changes, and the red corpuscle count falls to or below 1,000,000 per c.mm.

Leukopenia and relative lymphocytosis common.

Found earlier in life.

Gastric symptoms not so prominent.

Lemon-tinted skin common.

Adipose tissue fairly well preserved.

No glandular enlargements palpable.

No physical signs over stomach.

Examination of gastric contents after test-meal usually negative.

Some improvement may be brought about—even cure, though very rarely.

May show retinal hemorrhages.

From *chlorosis* the affection may be differentiated easily by the blood-examination. The relative increase in hemoglobin, the presence of giantoblasts and many macrocytes, and the severe oligocythemia are pathognomonic of pernicious anemia, and are in marked contrast to the oligochromemia, and slight, if any, reduction in the number of red globules of chlorosis. Again, the progressive pernicious character of the former and the tendency to hemorrhage should be remembered, as well as the contrasting factors of age and sex in the two affections. Talley¹ states that anemia secondary to portal cirrhosis without hemorrhage occasionally resembles progressive pernicious anemia. *Tabes dorsalis* may be simulated, but the blood examination will show characteristic indications of pernicious anemia.

Prognosis.—The disease, as a rule, terminates fatally, though not so frequently now as at one time, for obvious reasons. The course of pernicious anemia is usually slow and gradual, and may be interrupted by improvement or apparent recovery. Recurrences, however, invariably occur. Idiopathic anemia is therefore almost hopeless, although a few apparently substantial recoveries have been reported. The duration of the disease is seldom more than a year, and may not be more than two or three months. The nucleated red corpuscles usually become much more numerous shortly before death (Billings). Death may be caused either by syncope, cerebral hemorrhage, or by slow asthenia.

Treatment.—**Hygienic measures** must be regarded as of signal importance, and rest in bed, together with light nutritious food given at short regular intervals, is indicated first of all. Klemperer advises a fatty diet—one liter of cream and 200 grams of butter per diem. Salt-water baths and gentle and systematic massage are useful adjuvants. Fresh, open air is advisable when it can be taken.

The value of *arsenic* in this disease is, I think, analogous to that of iron in chlorosis. The best action of the drug will be obtained by the administration of gradually ascending doses of Fowler's solution. Beginning with four or five drops of the former, three times daily during the first week, and thereafter adding one drop to the dose every day or two up to the point of tolerance, as much as twenty or thirty drops, well diluted,

¹ *Jour. of the Amer. Med. Assoc.*, October 3, 1908.

OBSCURE GASTRIC CARCINOMA.

Blood shows characteristics of secondary anemia, and the count does not fall to 1,000,000, as a rule.

There may be leukocytosis or a relative increase in the polynuclear cells.

Occurs after middle life.

Gastric symptoms more suggestive.

Skin of a pale, muddy color, or only slightly jaundiced (saffron-yellow).

Progressive emaciation.

Supraclavicular or inguinal glands may be palpable.

There may be an area of increased resistance over the stomach.

Examination of gastric contents shows deficiency or absence of free hydrochloric acid and presence of lactic acid.

Condition becomes steadily worse until death ends the case.

Absent.

may be taken (see Fig. 37). Evidences of gastro-intestinal irritation should be watched for, and the arsenic discontinued temporarily should they appear. Sometimes it is advisable to use the remedy hypodermically. Arsenous acid is given in pill form, commencing with $\frac{1}{30}$ or $\frac{1}{20}$ gr. (0.0021–0.0032).

The introduction by Fraser of Edinburgh of bone-marrow in the treatment of pernicious anemia has been followed by various results: some cases have been reported in Great Britain and in the United States in which it has seemed to do good, while in others it was found to be useless. While the glycerin extract is the preparation generally used, it is not so reliable as the raw red bone-marrow, or that freshly prepared each day by mixing with it an equal quantity of glycerin; an ounce or two may be administered daily. Vetlesen has used glycerin—half an ounce with the juice of half a lemon, thrice daily—with success. Hunter suggests the use of antistreptococcus serum coupled with the antiseptic care of the mouth and gastro-intestinal antiseptics. Iron is unnecessary, as there are enormous quantities of it in the liver (Gulland).

FIG. 37.—Chart of a case of progressive pernicious anemia, showing the improvement following the administration of arsenic. Black, red corpuscles; red, hemoglobin.

Near the end of the disease the danger often greatly increases, owing to the marked reduction in the quantity of the blood (*oligemia*). This may be combated by the injection of warm water or a weak saline solution into the colon, and also into the subcutaneous tissue. Both the former procedure and gastric lavage are of value in ameliorating the gastro-intestinal disturbance from fermentation. *Intestinal antiseptics* (salol and beta-naphthol) should be given by the mouth. Grawitz¹ outlines a causal treatment; he eliminates animal albumin from the diet, administering fruit juices to supply the lack of hydrochloric acid. A daily lavage with a 1 or 2 per cent. solution of sodium chlorid and a daily colon irrigation are to be given. Bovaird² reports favorable results from transfusion of blood in cases in which the hemoglobin falls below 20 per cent.; it offers the possibility, not only of averting death, but for a time, at least, of initiating one of the periods of quiescence so characteristic of the disease.

Anthelmintics must be used in those cases of pernicious anemia in which intestinal parasites are associated. Morgenroth and Reicher³ have shown that experimental anemias in animals are benefited by administration of cholesterin, which they have employed in the treatment of pernicious

¹ *New York Medical Journal*, October 15, 1910, p. 777.

² *Medical Record*, February 11, 1911.

³ *Berlin. Klin. Woch.*, Oct. 12, 1908.

anemia to prevent hemolysis. A 3 per cent. solution of cholesterin in oil is prepared and 100 grams of this administered daily. Dilute hydrochloric acid and bitter tonics are serviceable in cases in which digestion is impaired.

Recurrences will yield to the same treatment, if they yield at all.

Aplastic Anemia.—Senator¹ has called attention to a form of pernicious anemia to which he gave the term *aplastic*. A variety of pathologic changes have been found. Blumer classifies these into three groups: (1) Cases in which the lesions are those of progressive pernicious anemia; (2) those cases in which the bone-marrow shows primary aplasia; and (3) cases in which there is a hyperplasia of the mononuclear elements of the bone-marrow.

The *symptoms* and *physical signs* are those of pernicious anemia, but the cases run a more rapid course—six to nine months. The blood findings are unlike those of pernicious anemia, nucleated red blood-cells being absent and the number of leukocytes greatly diminished. A differential count of the leukocytes shows the small mononuclear forms to be relatively increased 70 to 90 per cent., while the eosinophiles are few.

II. THE SECONDARY ANEMIAS.

The secondary anemias are symptomatic of abnormal processes or of existing disease, whether acute or chronic, and their causes are numerous and various. Several possible causes may exist in a given case of symptomatic anemia, and it may be quite difficult to discover which of these is the active factor in the condition. In certain secondary anemias, also, the associated impairment of the blood-making organs is so evident that the anemia may assume almost a primary importance.

The Blood.—There is *oligocythemia*, usually of a moderate degree, about 3,000,000 red corpuscles per cubic millimeter being noted, although in cases following hemorrhage the reduction may be as great for a time as in pernicious anemia. There is also a relative decrease in the amount of *hemoglobin*, and sometimes the percentage may be relatively lower even than is compatible with the decrease of the red corpuscles. Early evidences of secondary anemia are alterations in the viscosity (stickiness) of the red cells and failure to form *rouléaux* and an unequal distribution of the hemoglobin, certain cells being overcharged while others are inadequately supplied. Next in the process of degeneration of the red cell is irregularity in size and shape (microcytes, macrocytes, poikilocytes), and third is abnormal staining reactions (polychromatophilia, punctate basophilia). Lastly there appears abnormally large nucleated red cells (megaloblasts). Normoblasts are also present in severe cases. There is a relative, and often an absolute, increase in the number of *leukocytes*.

The most important etiologic groups of secondary anemias are as follows: (1) **Hemorrhage.**—Hemorrhages occur under a great variety of circumstances, and if copious, result in an acute secondary anemia. Thus there may be the rupture of an aneurysm, menorrhagia, post-partum hemorrhage, hemoptysis, gastrorrhagia, enterorrhagia, etc., all of which produce the same general effect upon the system. Repeated small hemorrhages may finally produce the same result as a single large one, and spontaneous hemorrhages or epistaxis, such as occur in persons of a hemorrhagic diathesis (hemophilia) or in purpura and scurvy, may cause profound secondary anemia. Females are most tolerant of losses of blood, but infants of both sexes bear depletion very badly. The total

¹ *Zeit. f. klin. Med.*, vol. liv., Nos. 1 and 2.

mass of blood may be much diminished (oligemia), and the sudden loss of a great volume of blood may prove fatal in a few moments; but it is often surprising how recovery can take place, and often does, after the rapid loss of several pounds of blood—*e. g.* in hemoptysis, hematemesis, or menorrhagia. Sometimes the source of bleeding is obscure, as in cases of intestinal parasites, hepatic cirrhosis, or duodenal ulcer; or it may be intentionally kept *sub rosa* by females having uterine disorder or bleeding hemorrhoids. The quick blanching of the counte-

FIG. 38.—Blood-chart of a case of symptomatic anemia. Black, red corpuscles; red, hemoglobin; blue, white corpuscles.

nance, the weakness, the coldness of the skin, faintness, dimness of vision, tinnitus aurium, sighing respiration, and feeble, rapid pulse are characteristic symptoms of *acute anemia*. *Unconsciousness* and *epileptiform convulsions* precede death in cases in which the total volume of blood lost is sufficiently large. When *recovery* takes place the blood-regeneration goes on rapidly, so that within from one to three weeks restitution is complete. The normal volume is soon restored—first by the absorption of water, hydremia existing for several days before the saline and albuminous elements are renewed. The white corpuscles are earlier restored than the red, so that there is a temporary relative leukocytosis. The hemoglobin is restored still more slowly than the red corpuscles.

(2) **Inanition.**—Anemia from inanition may be caused by a food-supply that is insufficient either in quantity or quality, or both; or, even with abundant food of sufficient nutritive qualities the digestive power may be so impaired as to cause defective assimilation. Esophageal

carcinoma and chronic gastritis, especially of the atrophic variety, may thus cause anemia from inanition. The reduction of the blood-plasma forms a feature, while the corpuscles may be affected but slightly.

(3) **Excessive albuminous discharges**, as in chronic Bright's disease, prolonged suppuration, long-continued lactation, chronic dysentery, etc., drain the system so that marked anemia may be produced.

(4) **Toxic Agents**.—The poisons may either be organic or inorganic, though toxic anemias are most common from the absorption of lead, arsenic, mercury, and phosphorus. The poisoning is usually chronic, and affects principally the corpuscles. Anemia due to the poisons of acute or chronic infectious diseases is also frequently met with, and may thus be observed during and after typhoid fever, diphtheria, yellow fever, and inflammatory (articular) rheumatism among the acute diseases, and during chronic malaria, tuberculosis, and syphilis ("syphilitic chlorosis"). There is considerable destruction of the red corpuscles in some of these diseases, either directly or indirectly, and the greater the pyrexia the greater the action upon the blood or blood-making organs.

Symptoms.—The *common indications* of secondary anemia are the pallor of the face and mucosæ, muscular and mental weakness, loss of nerve-function, neuralgias, coolness of the skin, dyspnea on exertion, cardiac palpitation, impaired appetite and digestion, and a weak pulse. The physical signs are those of the primary or essential anemias.

Diagnosis.—Here may be advantageously contrasted the distinguishing features of symptomatic and essential anemias, respectively :

SYMPTOMATIC OR SECONDARY ANEMIA.

A symptomatic blood-condition secondary to a detectable disease elsewhere.
Occurs at any age.

Previous or associated history of traumatic or spontaneous hemorrhage, chronic suppuration, prolonged lactation, chronic Bright's disease, carcinoma, chronic lead-poisoning, chronic malaria, heart, liver, or gastric trouble.

Blood-changes not so marked and more variable; steadily progressive in malignant disease.

Moderate reduction in both, merely the relative proportion being maintained.

General symptoms and signs usually subordinate in manifestation to those of the primary disease or lesion.

Gravity of anemia depends on that of the primary disease.

Often responds to treatment, depending on the cause; in a few instances, as in hemorrhage, it is short in duration.

IDIOPATHIC OR ESSENTIAL ANEMIA.

A primary disease of the blood and blood-making organs.

Occurs principally during adolescence and early middle life.

Previous history negative in its bearings upon the disease.

Distinctive blood-characteristics, and often profound changes, both as to blood-cells and hemoglobin.

Marked reduction in both the hemoglobin percentage and in the number of red corpuscles, but the proportionate ratio is lost.

General symptoms and signs also more characteristic of the respective form of anemia in the case.

Gravity depends on type of blood-changes and progressiveness of disease.

One variety (chlorotic) quite curable, the other (progressive pernicious) relapsing, and finally fatal.

The **prognosis** depends upon the cause of the anemia.

Treatment.—Symptomatic anemia is amenable to treatment according to the cause. The traumatic acute variety does well under simple hygienic measures after the urgent indications have been met. Plenty

of pure air, wholesome food, and graduated rest and exercise may suffice, and drugs not be needed. Cases in which it is difficult or wellnigh impossible to remove the cause of the anemia of course do not improve under any treatment other than that which may favorably influence the primary affection. Nutritious aliment, iron in some form, a judicious hygienic regimen calculated to increase the assimilation, and stomachic and general tonics are required in the majority of cases. Toxic substances must be eliminated, their re-introduction into the body prevented, and the repair of the blood and tissue actively promoted.

LEUKEMIA.

(*Leukocythemia*.)

Definition.—A blood-disease, usually chronic, characterized by a peculiarly marked and persistent increase in the number of leukocytes, associated with lesions occurring either respectively or unitedly in the bone-marrow and lymphatic glands.

Pathology.—Bodily emaciation and pallor are pronounced, and edema, with dropsical effusions in the serous cavities, is by no means uncommon. The cardiac chambers and principal veins are distended with large blood-clots of a greenish-yellow or, in extreme cases, yellowish-white, purulent appearance. Subserous ecchymoses of the pericardium and endocardium are frequent, and the myocardium is often found to have undergone a moderate degree of fatty degeneration. Various abnormal substances have been found in leukemic blood—leucin, tyrosin, acetic, formic, and lactic acids, and certain albuminous substances (deutero-albumose and nucleo-albumin)—resulting probably from the destruction of blood-corpuscles. The alkalinity of the blood is diminished. The minute, octahedral (Charcot's) crystals are found most abundantly in settled leukemic blood, and have also been detected in the spleen, bone-marrow, and liver, as well as in other affections.

Although the bone-marrow or the lymph-glands may alone show the pronounced pathologic changes of leukemia, it is usual to find both more or less affected. It is customary to speak of two principal groups: (1) *myeloid* leukemia, the more frequent variety; and (2) *lymphoid* leukemia.

There is nearly always some splenic enlargement, and in many cases the enlargement is considerable. Leukemic spleens sometimes weigh as much as from two to eighteen pounds, and their lengths may vary from six to twelve inches. The enlargement is generally uniform, and the notches upon the anterior border may be much exaggerated. White patches of perisplenitis and a thickened capsule adhering to the surrounding organs and the abdominal wall may also be noticed. The consistence of the spleen is firm and resistant to the knife, though in the earlier stages it may be quite soft and pulpy. The cut surface is either of a uniformly brown color or mottled by the presence of grayish- or yellow-white circumscribed lymphoid tumors, or by deep-red or brownish-yellow hemorrhagic infarcts. The Malpighian bodies may or may not be visible. The blood-vessels at the hilum are enlarged. *Microscopic examination* shows hyperplasia of the organ. The cells of the pulp sometimes show granular and fatty degeneration, and in advanced cases the trabeculae may be thickened by connective tissue. Ewing believes that the splenic enlargement is due to the mechanical sifting of the red and white cells from the circulation with subsequent inflammatory changes.

In the majority of cases the bone-marrow is the primary seat of the disease in the myeloid variety. The medullary substance, instead of being fatty, is rich in lymphoid and blood-cells in various stages of development, and is either reddish-brown or greenish-yellow in color. Neuman regarded the marrow change as an essential lesion of leukemia, and called the former transformation "lymph-adenoid" and the latter "pyoid." The pus-like marrow and the dark red may exist side by side, although the former is more common.

A fine reticulum may be seen between the cells, especially in the dark-red variety, and small hemorrhagic infarcts may also be noted occasionally. *Microscopically*, the medulla contains an abundance of lymphoid cells and nucleated red corpuscles. Eosinophilic, mononuclear, and polynuclear leukocytes are also present, the first-named being quite numerous, as are also certain myelo-plaques and cells showing karyo-kinetic figures. The *lymphatic glands* are more or less enlarged in the myeloid form of leukemia.

In the **lymphoid variety**, especially when acute, an early and marked hyperplasia of all the glands takes place, and may form distinct, soft, and movable tumors, their color being a reddish-gray.

The histologic examination shows an increase in the cellular elements. A similar hyperplasia occurs in those glandular tissues that are allied to the lymphatic glands, such as the tonsils, lymph-follicles, the tongue, mouth and pharynx, thymus gland, the solitary and Peyer's agminated intestinal glands, and the Malpighian bodies in the spleen.

Proliferation of the bone-marrow cells, which are carried to other tissues and there multiply, is the essence of the disease. Available space for the production of red cells is encroached upon by lymphocytic proliferation, hence the anemia.

The *liver* may be greatly enlarged; indeed, some of the instances of greatest enlargement of this organ have been those due to leukemia, the weight being as much as fourteen pounds. The enlargement is uniform and due to a diffuse leukemic infiltration. The capillaries and interlobular tissue are distended with leukocytes, and disseminated whitish or grayish nodules, usually quite small, consisting of lymphoid cells undergoing indirect division of their nuclei, are frequently found. Sometimes these leukemic nodules appear as definite growths, with an adenoid reticulum between the cells (lymph-adenomata).

Similar changes are observed in the *kidneys*, enlargement, paleness, and diffuse and circumscribed leukemic infiltration of the capillaries and interlobular tissue all being noted. Leukemic nodules may also be found in other parts of the body, such as the retina, brain, serous membranes, lungs, testicles, and skin. Karyokinetic figures are numerous in the cells accompanying these leukemic growths.

Etiology.—The primary cause of leukemia is unknown; that it directly affects the blood-forming organs, however, is most probable, though with differences of selection and co-ordination and with different degrees of intensity. The combination of lesions in the spleen, lymph-glands, and bone-marrow, along with the histologic similarity of the leukemic growths to the infectious granulomata, and the clinical history of cases of acute leukemia, would seem to point strongly to the *microbic origin* of the disease. Moreover, various cocci and bacilli have been found, but not one of them has been definitely proved to be the specific cause of the disease. *Auto-intoxication* by toxic albuminoids from the

digestive tract is believed by Vehsemeyer,¹ who analyzed 600 cases, to be the important point of departure of the disease. It is likely that the direct cause of the leukocythemia is a simple increase of the cytogenic function of one or more of the hematopoietic organs. Kottnitz held leukocythemia to be a reactive condition following auto-intoxication with peptones, and consequently a leukolysis, the over-action of the hematopoietic organs leading to hypertrophy. Whether the reduction of the erythrocytes is due to diminished production or to increased destruction is not positively known, although the former factor is more probably operative.

The disease has often been preceded by an *injury* or a *blow* in the splenic region, but its direct traumatic origin is hypothetic only. *Intestinal ulceration* has been a frequent feature prior to leukemia, and undoubtedly affords a source of possible infection from the tract. *Stomatitis* also may furnish a means of entrance for the infectious agent. The causal relation of *pseudo-leukemia* and *true leukemia* is uncertain, although a few cases of the one have been observed to pass into the other.

In a considerable proportion of cases leukemic patients have had *malaria* of some form. Syphilis may be associated with the disease, but it is not probable that it acts in a causative manner.

Hereditary influences undoubtedly play a part; a "lymphogenous diathesis" may thus be transmitted, and several generations may be affected by the disease. *Adverse hygienic and social conditions* may also predispose to leukemia. It may also develop after *pregnancy*, or more commonly at the *climacteric*. Anxiety, worry, and mental depression have been mentioned as predisposing causes, with doubtful justification.

Leukemia occurs most frequently in males during the middle period of life, and is apt to attack young persons. It has occurred during infancy, and as late also as the seventieth year, but the average age ranges from twenty-five to forty-five years. Sometimes the previous condition was one of apparently perfect health.

Symptoms.—*Acute leukemia*, comparatively rare, usually occurs in an adolescent who may have enjoyed previous good health. Fussel and Taylor collected 56 cases from the literature. Hamman tabulated 111 cases, and in several affections of the mouth or throat were observed at the commencement. Its onset is sudden, and usually begins with prostration, hemorrhage of the mucous membranes, and high fever. Acute splenic tumor rapidly develops; the lymphatic glands may enlarge; and palpitation, dyspnea, and gastro-intestinal symptoms of a severe type appear. The skin becomes anemic, and edema of the feet is common. The blood shows a marked increase in the number of leukocytes, the ratio to the red corpuscles being 1 to 30 or 1 to 50, instead of the normal 1 to 350 or 1 to 600. In *acute lymphoid leukemia* the lymphocytes are very numerous. In *acute myeloid leukemia* there is an increase in the blood of a cell originating from the myelocytic cells of the bone-marrow, representing the ancestor of the myelocytes and granular leukocytes, which are numerous in the blood picture. The case grows progressively worse; hematemesis, cerebral or retinal hemorrhages, and petechiæ supervene perhaps, and the clinical features may then resemble an infectious disease with hemorrhagic and purpuric manifestations. Early in life the hemorrhages are less common and the increase in lymphocytes is apt to concern the small variety of cells.

In *chronic leukemia* the *onset* is generally slow and insidious and for

¹ *International klin. Rundsch.*, Vienna, Nov. 25, 1894.

many months the earlier symptoms may not differ from those of simple anemia. Languor, a deranged appetite, dizziness, noises in the ears, faintness, breathlessness on exertion, and palpitation may all appear. Sometimes, however, not even these symptoms are present, common as they are to most anemic cases, and the patient may first consult the physician, because of a swelling or distress in the left side of the abdomen—the *enlarged spleen*. Early manifestations may be *hemorrhagic* (epistaxis, hematemesis, enterorrhagia), with nausea, vomiting, and diarrhea; or *increasing pallor* of the countenance, yet at times a patient may appear to be plethoric; or troublesome priapism may appear. As the disease progresses the anemia becomes more marked, *edema* of the dependent portions of the body may appear, and *fever*, though slight at first (99.5° F.— 37.5° C.), may gradually rise to 102° or 103° F. (39.4° C.), either remaining constant or alternating with periods of *apyrexia*.

The *pulse-rate* is increased; in quality it is soft and compressible, though sometimes full in volume. The *dyspnea* may be aggravated by the hydrothorax in advanced cases, or by the upward displacement of the diaphragm owing to the increasing splenic and hepatic enlargement. *Epistaxis* may become obstinate. Retinal hemorrhage is common, and there may be aggregations of leukocytes (leukemic growths). Hemorrhages from mucous membranes are common, and localized gangrene may occur, with the symptoms of infection. Hemic murmurs are quite constant.

Ulcerative processes in the bowels may give rise to severe *dysenteric diarrhea*. *Ascites* is usually present in advanced cases on account of the splenic tumor, or owing to pressure upon the portal vein by enlarged glands. *Jaundice* is an occasional event. *Leukemic peritonitis* may occur from the presence of lymphomatous growths in the membrane.

Nervous symptoms, such as headache, vertigo, and syncopal attacks, recur as the anemia and prostration increase and the liability to hemorrhage becomes more frequent. Sudden coma and hemiplegia following upon the rupture of a cerebral vessel (apoplexy) may be the immediate cause of death. Minute brain-hemorrhages may account for deafness. Priapism may be troublesome. Peripheral paralysis of several cranial nerves, due to hemorrhages into their sheaths, has been reported.

Cutaneous ecchymoses are sometimes observed, and sometimes there is a troublesome pruritus. The *urine* contains an excess of uric acid, but albuminuria does not occur, except as a complication.

Along with the anemia and debility are the signs of splenic and lymphatic involvement, and rarely of the bone-marrow. The liver may also become enlarged.

Leading Symptoms in Detail.—*The Spleen*.—This organ is generally enlarged in all forms of leukemia, but especially in the spleno-medullary, the most frequent form. It is a prominent feature, both on account of its being the first subject of complaint, and because of the huge size it frequently attains. The enlargement is gradual, and there may be neither pain nor tenderness over it. The tumor may cause a visible projection below the ribs, and in marked cases great abdominal distention may be produced, pushing up the diaphragm and thoracic organs, and extending to the navel in the median line and to the pelvis below, in which case the cardiac pulsation is seen at the second or third interspace. The edge and notch or notches may be felt easily in such instances, while the surface is smooth and the consistence firm. A friction-

fremitus is felt sometimes during respiratory movement. The tumor may vary in size, and after severe hemorrhage or diarrhea it may become swollen. Gastric distress after eating and obstructive constipation are usually complained of in cases of great splenic enlargement. Jaundice may also be present. Pulsation has been noted and a systolic murmur—"splenic souffle"—has been heard at times over the tumor. The percussion-note is dull over the tumor, and areas of movable dullness, due to fluid occupying the peritoneal cavity, are not infrequent. A wave of fluctuation may be detected over the abdomen. The liver is often enlarged.

Lymphatic Glands.—In the splenic-lymphatic variety, which is less common than the splenic-myelogenous, and in the still rarer purely lymphatic leukemia, the superficial lymph-glands may be both visibly and palpably enlarged, though not in bunches as in Hodgkin's disease. They are soft, resilient, and movable.

The Bones.—Purely myelogenous leukemia is very rare, and local bone-symptoms are scarcely ever manifested. There may be some tenderness on immediate percussion over the sternum or some of the long bones, and slight swelling, irregularity, or deformity of the ribs, the sternum, or other bones may result from leukemic hyperplasia.

The Blood.—It is by the blood-examination alone that the pathognomonic features of leukemia are determined. The blood is paler than normal, and sometimes has a brownish-red or chocolate color. Upon a microscopic examination of the blood in the myeloid form of the affection the striking increase in the number of leukocytes is observed at once. The count shows usually from 85,000 to 500,000 white corpuscles per cubic millimeter, and the ratio of the white to the red cells may thus vary from 1 to 150 down to 1 to 10 or 1 to 5 in the average case, instead of the normal, 1 to 500 (see Fig. 40). In extreme cases the number of leukocytes may be equal to, or even slightly greater than, that of the erythrocytes, and such an instance has been recorded by Sørensen, in which the proportion of whites to reds was 3 to 2.

Stained specimens of the blood enable us to recognize the variety of leukemia (Fig. 39, Pl. V.). Thus, in the ordinary myeloid form the characteristic change is the presence of the abnormal *myelocytes*—large, mononuclear leukocytes with the protoplasm filled with fine neutrophilic granules. These may make up 25 per cent. of the white cells, whereas they do not occur in normal blood, and very rarely, and only in small numbers, in leukocytosis. They probably correspond to the cells found in the bone-marrow, the large, oval, and eccentrically placed nuclei of both blood- and marrow-cells showing karyokinetic figures. The polymorpho-nuclear leukocytes may be normal in number, but usually they are relatively diminished to about 65 per cent. instead of 75 per cent., as in normal blood. The polymorpho-nuclear cells showing coarse basophilic granules are increased, and may equal in number the eosinophiles. When Ehrlich's triacid stain is used these cells appear as non-granular polynuclear bodies. The lymphocytes are also relatively less in number, making up but 1 or 2 per cent., instead of the normal 15–30 per cent. The bright, acid-stained eosinophiles, though absolutely increased, are not always relatively so. They possess but little diagnostic value, being common to many other conditions.

Moderate *oligocythemia* is noted in the later stages, the reduction

FIG. 39.—Fresh preparation from the blood of a case of leukemia ($\times 550$); large mononuclear leukocytes of immature form.

[Grawitz.]

being seldom lower than to 2,000,000 per c.mm. The percentage of hemoglobin may also be reduced relatively or in slightly greater proportion. Nucleated red corpuscles, chiefly normoblasts, are invariably found. Cells with large, pale nuclei are occasionally found, and cells with fragmented nuclei are common. Gigantoblasts may be present. Blood of the type of pernicious anemia may subsequently develop a true leukemia. In a majority of cases the blood-plates are considerably increased.

In *lymphatic leukemia*, which is rarer and more quickly fatal than the preceding variety, the *lymphocytes* are increased, all other leukocytes being relatively much diminished in number. Instead of the normal percentage (15 to 30 per cent.), the lymphocytes may number from 90 to 97 per cent. of all the leukocytes. The excess of leukocytes,

FIG. 40.—Blood-tracing of a case of leukemia. Black, red corpuscles; red, hemoglobin; blue, white corpuscles.

however, is less than in the myeloid form. This increase affects the small forms in most cases. Cabot has shown that in some instances this increase affects the larger lymphocytes. Nucleated red corpuscles, chiefly normoblasts, are present in small numbers. Myelocytes are not numerous, but quite constant. The erythrocytes show changes in size, shape, and staining out of proportion to the degree of anemia present. Eosinophiles are relatively diminished. *Mixed forms* of leukemia are not at all uncommon, so that the proportions of the various types of normal and abnormal cells are quite variable.

The *blood-plates* may be quite abundant in many leukemic cases, and Charcot's octahedral crystals appear in specimens of the blood on standing. An unusually dense and thick fibrous network is also often found.

Complications.—Fatal hemorrhages may occur at any time, pleu-

ritis, pneumonia, septicopyemia, renal disease, severe diarrhea, toxemic jaundice, and edema may complicate leukemia and cause death.

Dock¹ has shown that chronic tuberculosis does not distinctly influence the course of leukemia. Acute miliary tuberculosis, however, may follow and also cause a reduction of the leukocytes.

Diagnosis.—This can be made accurately by the blood-examination alone, the distinguishing characteristics of the blood having been enumerated above, both as to the existence of leukemia and the differentiation of its several varieties. Stained specimens of the blood should be studied, since the excess of leukocytes alone is not proof of leukemia, and also because the disease may exist without an excess, owing either to previous medicinal treatment or to temporary improvement.

Differential Diagnosis.—Leukemia is differentiated from a marked *leukocytosis* by the fact that in the latter there is usually a more moderate increase in the number of leukocytes, affecting, as a rule, principally the polynuclear neutrophils; in addition myelocytes are absent.

Hodgkin's disease may be simulated by the purely lymphatic leukemia on account of the enlarged glands; but in leukemia the lymph-glands are not found in such large bunches, and the blood-examination will show the characteristic changes of lymphatic leukemia if that disease be present. Simply a leukocytosis is present in pseudo-leukemia.

Malignant growths of the spleen and lymphatic glands, and also a malarial and passively congested spleen with anemia, may simulate leukemia. Here again the blood-examination will exclude leukemia.

Prognosis.—Many cases are mild in their progress; children, however, when affected, succumb more rapidly than do adults. Lymphatic leukemia is always fatal earlier than the spleno-medullary variety, and in severe acute cases the larger lymphocytes are found. Although recovery does occur occasionally, most cases of leukemia, of whatever form, prove fatal certainly within five years, generally in two or three years, and sometimes in seven or eight months or even less (from two weeks to two or more months) in acute leukemia. In an advanced case the prognosis is hopeless. Grave symptoms heralding an early termination are profound debility, anemia, emaciation or edema, severe and obstinate hemorrhages, cerebral apoplexy, persistent diarrhea, and high fever. Intercurrent affections not infrequently cause death, while, on the other hand, cases are recorded in which the appearance of intercurrent infectious diseases (erysipelas, enterocolitis, pleuritis) has favorably affected the course of leukemia. Remissions may rarely occur.

Treatment.—At present no remedies are known to have any permanent curative effect. The application of the Röntgen ray over the spleen, sternum, and extremities of the long bones (viscera 10-minute exposures, joints 5-minute exposures), at first suggested by N. Senn,² is followed by: disappearance of the fever; decided decrease in the volume of the spleen; increase in the number of red cells and in the hemoglobin. The leukocytes are at first reduced and may fall to near the normal number, but later the blood again becomes leukemic. Oettinger, Fiessinger, and Sauphar³ claim that radiotherapy produces a leukolytic ferment, which by disintegrating the corpuscles, may transform chronic myelogenous

[L. Napoleon Boston.]

leukemia into an acute phase, or pernicious anemia. Warthin¹ believes that the Röntgen-ray treatment of leukemia finds a pathologic basis in the selective action which the rays have for cells of the lymphocytic and myelocytic types. Larrabee² has used the mixed toxins of Coley in 4 cases with results encouraging enough to warrant further trials.

The environment should be made as favorable as possible—physically, mentally, socially, and morally. Out-of-door life in a mild, dry climate, an abundance of nutritious and easily digestible and assimilable food, calm and moderate exercise of mind (depending upon the endurance of the patient), should all be advised and encouraged. On the other hand, traumatism, irregular habits of body, worry, excitement, and passionate emotions and appetites should be regulated and avoided.

Arsenic gives the best results in most cases, and should be pushed to the limit of tolerance, as in pernicious anemia. It should be given continuously, regardless of apparent improvement under its use, as the latter may be only the natural remission—a not uncommon incident in the disease. Bone-marrow, either raw and spread upon bread, or in the form of a glycerin extract, may be tried when arsenic fails. Oxygen-inhalations and blood-transfusion have been suggested. The so-called “splenic remedies,” whether systemic or local, have no controlling influences upon the disease. Complications may be relieved by appropriate treatment.

LEUKANEMIA.

So-called “leukanemia” (Leube) is most probably either leukemia with terminal anemia, or pernicious anemia with lymphoid or myeloid marrow (Cabot).

CHLOROMA.

Pathologically, it consists of a sarcomatous growth, the primary seat of which is in the periosteum and bone in and about the orbit. Threadgold holds that the bone-marrow is primarily affected in chloroma. The growth shows a pea-green pigmentation. Secondary growths may be widespread. Gulland and Goodall claim that there is no histologic difference between chloroma and lymphoid leukemia. Myeloid chloroma also occurs, 10 cases having been recorded by Jacobaeus.³

Symptoms.—Pain in the orbital region, exophthalmos, and deafness are noted early. The principal diagnostic features are gangrenous stomatitis and often a high-grade anemia, usually associated with a hemorrhagic diathesis. There is some enlargement of the lymphatic glands and spleen. In the lymphoid form there occur the tumor-like infiltrations of the orbit and other parts of the skull, and it is seen in children. The blood-picture is that of lymphoid leukemia.

The myeloid form is characterized by the presence of neutrophilic myelocytes, making up from 50 to 95 per cent. of the cells, and a marked leukocytosis. It seldom shows tumor growths.

The *course* of the disease—spoken of by French writers as “green cancer”—is rapid, and death usually comes on within a few months. The Röntgen rays have given marked improvement in the *treatment* in some cases, but not in others.

PSEUDO-LEUKEMIA.

(Hodgkin's Disease; General Lymphadenoma.)

Definition.—An anemia characterized by the anatomic peculiarities resembling those of lymphatic leukemia—viz., progressive hyperplasia of the lymph-glands, occasional secondary lymphoid growths of other organs (liver, spleen); and by the absence of the destructive blood-changes of true leukemia.

Varieties.—Although the disease that bears his name was first described by Hodgkin of Guy's Hospital in 1832 as an affection of the lymphatic glands and spleen, two varieties are included under the title of pseudo-leukemia (or Hodgkin's disease), as follows: (1) that which presents simply an enlarged spleen (the less frequent one); and (2) that in which the lymphatic glands are chiefly involved.

Pathology.—The lymph-glands show different degrees of hyperplastic enlargement and consistency. In the earlier stages they are small, isolated, and movable, while in advanced and well-developed cases of the disease they are larger, fused together into great bunches, and more or less fixed by fibrous investment. As a rule, the glands are soft and elastic, though sometimes they are hard and dense, and masses as large as an orange or pineapple may be seen. Single glands may be as large as a hen's egg, and the gland-capsules may show connective-tissue proliferation and a thickening periaadenitis. Extension of the lymphatic growth into the surrounding tissues by perforation of the capsule may occur. As a rule, the overlying skin is freely movable, though it may rarely be adherent. On section the tumors display a smooth white or reddish-gray surface in the case of the soft and almost fluctuating glands, and a grayish or a yellowish-white color if they are firm. The fusion of the swollen glands into nodular masses is also seen, and when ulceration through the skin has taken place suppuration of the glands may be revealed. In the harder tumors areas of necrosis having the appearance of caseation, and shining masses of fibroid tissue may be visible.

Microscopically, there is a typical hyperplasia of the lymph-cells often obscuring completely the reticulum of the gland, except in the harder enlargements, where the fibrous proliferation shows a very distinct network. The change is a lymphadenoma of the lymphatic glands. Reed¹ states that the true form of the disease has a specific histology, showing large numbers of eosinophiles and a peculiar variety of giant-cell, different from that of tuberculosis. Longcope, Ruffin,² and others also believe that the disease shows histologic changes peculiar to itself. Gibbons,³ on the contrary, is strongly inclined to the malignant theory.

The cervical glands are most prominently involved. The superficial chains of glands—axillary, mediastinal, scapular, and pectoral—especially along the great vessels, are often found connected, and the inguinal, bronchial, and lumbar glands are also affected, though less frequently. The retro-peritoneal glands are more frequently affected than the mesenteric; they have occasionally projected externally by perforation through the sternum.

The *spleen* is enlarged in about four-fifths of the cases, but only slightly. In the majority of cases there are disseminated throughout the organ whitish, lymphomatous growths or nodules from the size of a pea to that

¹ *Johns Hopkins Review*, vol. x., p. 133.² *Amer. Jour. Med. Sci.*, April, 1906.³ *Amer. Jour. Med. Sci.*, November, 1906.

of a nut. Their histologic structure is like that of the lymph-glands (lymphadenoma). Occasionally the spleen alone is hyperplastic.

Lymphomata may also develop in the tonsils, lingual follicles, intestinal lymphatics, liver, kidneys, lungs, brain, spinal cord, heart, testicles, retina, and skin. The bone-marrow often appears the same as in pernicious anemia.

Etiology.—There are no well-established *predisposing conditions* to which Hodgkin's disease is referable. In 75 per cent. of cases males are affected, and young and middle-aged persons—between the ages of ten and forty years. In an analysis of 100 cases 30 were under twenty years, 34 between twenty and forty, and 36 after forty (Gowers). Heredity may possibly be a cause. The disease would seem to belong to the group of infectious granulomata, but the *exciting cause* is not known. Flexner thinks that certain protoplasmic foreign bodies (found in the larger nodules of two cases) may possibly have a causal relation. Malaria, syphilis, chronic skin-diseases, and various irritative conditions, especially of the mouth, giving rise to local glandular swellings, have also been assigned as causes. In undoubted instances of Hodgkin's disease the lymphatic glands frequently harbor tubercle bacilli; hence it has been thought that the latter exercise a distinct causative influence.

FIG. 41.—Temperature-chart of a case of pseudo-leukemia.

It must be remembered, however, that some of these may be examples of secondary accidental infection; others of primary diffuse lymphatic tuberculosis, indistinguishable from or mistaken for Hodgkin's disease. Musser¹ thinks "the disease is not improbably an expression of lymphatic tuberculosis." Sailer² arrives at much the same conclusion. Reed³ believes true Hodgkin's disease is not due to the tubercle bacillus, but that it is of infectious origin. It is not uncommon to find pseudo-leuke-

¹ *Amer. Med.*, Jan. 4, 1902.

² *Phila. Med. Jour.*, April 5, 1902.

³ *Loc. cit.*

mia developing in a person who immediately preceding the beginning of the disease was apparently in perfect health.

Symptoms.—Usually the first thing to attract attention is the enlargement of the submaxillary and cervical glands, often on one side of the neck alone. These grow gradually until they may finally appear on both sides as large as a fist, and produce considerable disfigurement. Sometimes several years may elapse before other glandular groups are affected, but, as a rule, it is a matter of months only before the axillary, then the inguinal, and perhaps the internal, glands are invaded. The changes vary greatly in rapidity and extent.

At first the *general health* may be but slightly affected. A little constitutional disturbance and some pallor may be complained of, though seldom before the glandular swellings are noticed. Then as the disease progresses the paleness increases and all the symptoms of a marked anemia appear—languor, failure of physical strength, beginning emaciation, gastro-intestinal derangement, headache, giddiness, palpitation, dyspnea, and edema of the legs. Later, the serous cavities contain effusion and there is a tendency to *hemorrhages*. Epistaxis and metrorrhagia may occur, and petechial spots, especially on the lower extremities, are not infrequent. The *physical signs* of anemia—hemic murmurs—are also present. An irregular slight or moderate pyrexia is common to most cases. Fever of a peculiar intermittent type has been observed, the intermissions and paroxysms each lasting for several days or weeks (see Fig. 41), and the term “chronic relapsing fever” has been applied in consequence. When these pyrexial exacerbations occur the cases generally run a more acute course. Ague-like paroxysms may persist for even months, as described by Pel, of *Amsterdam*.

The symptoms due to *mechanical compression* by the lymphomata are varied and numerous, depending upon the number, size, and distribution of the tumors. Hundreds of tumors may be present throughout the body, but, unless they press upon the adjacent nerves, the glands are not usually painful. Enlargement of the tracheal and bronchial glands may cause dysphagia, dyspnea, thoracic pain, disturbed phonation, and venous congestion, by pressure respectively upon the esophagus, trachea, bronchi, thoracic nerves, recurrent laryngeal nerves, superior vena cava, and the jugular veins. The obstruction to respiration may become so great as to produce death by suffocation.

Circulatory Symptoms.—*Congestion* of the head and upper extremities may be quite marked, and in such cases compensatory dilatation of the superficial veins is observed. *Edema* of the hand and arm may result from venous obstruction due to the pressure of very large axillary glands. The *heart's action* may be disturbed by pressure on the pneumogastric, and the heart itself may be dislocated by great gland-tumors within the chest. Under such circumstances the latter may be detected by dulness on percussion over the anterior mediastinal space.

Edema of the feet and legs may be an early indication of enlarged abdominal glands pressing upon the femoral veins. Albuminuria is not uncommon; ascites and hydrothorax are late conditions. *Jaundice* is sometimes attributed to pressure upon the bile-duct. *Gastro-intestinal disturbances* may be troublesome, and are usually symptomatic of lymphoid growths in the stomach and bowels. In thin individuals gland-masses may be palpable over the abdomen. Deafness may be caused by growths in the pharynx.

Nervous Symptoms.—Inequality of the pupils and unilateral sweating of the face, owing to glandular pressure upon the cervical sympathetic, may be noticed in some cases. Sharp lancinating pains along the nerves may also be felt. *Pressure-paraplegia* and *neuralgic pains* variously distributed throughout the body should also be mentioned among the nervous manifestations.

Cutaneous Symptoms.—It has been suggested that the bronzing of the skin sometimes seen in Hodgkin's disease may be due to the pressure of enlarged glands upon the suprarenal capsules. An intense pruritus has been complained of, and the skin may be erythematous. Occasionally the thyroid and thymus glands are involved.

Spleen.—The slightly or moderately enlarged spleen can usually be felt just below the ribs, projecting toward the navel. Tenderness over the spleen and bones may be elicited. The characteristic feature in splenic pseudo-leukemia is the decided enlargement of the spleen without involvement of the lymphatics.

The *blood* shows a moderate diminution in the number of red corpuscles, and a corresponding diminution in the hemoglobin, the former in most instances numbering from 2,000,000 to 4,000,000 per cubic millimeter. There may be more or less leukocytosis, and sometimes the lymphocytes may preponderate relatively; if the latter be present in great numbers, the blood may show similarity to that of lymphatic leukemia. An occasional normoblast may be seen.

Diagnosis.—Pseudo-leukemia is more readily confused with *tuberculous adenitis* than any other disease, particularly at the outset. Although an acute tuberculous adenitis may very closely simulate Hodgkin's disease and render a diagnosis almost impossible, more often the glands of tuberculous adenitis are slower in enlarging and extending than in this disease. In fact, extension of the lymphatic enlargements of tuberculosis is rarely seen as compared with pseudo-leukemia. Again, tuberculous adenitis is most common in the young, is unilateral rather than circumferential in the neck, and attacks the submaxillary glands oftener than the cervical chains along the sterno-cleido-mastoid. Again, periadenitis, adhesion, and suppuration of the glands occur in tuberculosis. Tuberculous foci in other organs may also be found. Intermittent attacks of pyrexia are an indication favoring Hodgkin's disease. In doubtful cases a gland may be removed for microscopic examination. The tuberculin test will exclude glandular tuberculosis.

The blood should be examined in order to differentiate from *leukemia*.

Syphilis must be carefully excluded by the history, symptoms, and therapeutic test. *Neoplasms* of the lymph-glands may sometimes be difficult to distinguish from pseudo-leukemia.

The diagnosis of *splenic pseudo-leukemia* is to be made on the decided splenic enlargement without involvement of the lymphatics. The following conditions, however, must be distinguished: (a) Pernicious anemia with enlargement of the spleen; this is readily done by a blood-examination; (b) Cirrhosis of the liver, in which there is splenic enlargement; (c) The splenic tumor of chronic malarial poisoning. Here the blood should be repeatedly examined for the organism of Laveran, if the patient resides in a malarial region; (d) Idiopathic enlargement of the spleen without any anemia.

Prognosis.—This affection runs an almost invariably fatal course. The remissions and exacerbations of the disease are, however, notable. In some

cases the termination may occur in a few months, but usually death ensues after the lapse of two or three years. It should be remembered that some instances of Hodgkin's disease seem to merge into a true lymphatic leukemia.

Grave indications are the rapid extension of the glandular enlargements, great debility, anemia, emaciation, steadily increasing and continuous pyrexia, thoracic pressure-symptoms, hemorrhages, and marked anasarca. Sometimes the tumors diminish greatly before death. In certain cases general streptococcus infection, intercurrent diseases, or such complications as empyema or nephritis, may be the immediate cause of death.

Treatment.—Surgical treatment is of no avail. It is claimed that exposure of the enlarged glands to the Röntgen ray is followed by a decrease in glandular enlargements and an improvement in all symptoms.¹ Hygienic measures and the use of all possible agencies to support the strength of the patient should be resorted to, and the administration of arsenic in gradually ascending doses, as for pernicious anemia and leukemia. The value of Fowler's solution is undoubted in many cases. Phosphorus has also been recommended, and the galvanic current may be applied topically. Tonics, nutrients, and red bone-marrow are of service.

ANÆMIA INFANTUM PSEUDO-LEUKÆMICA.

Definition.—The above title was given by von Jaksch to a form of anemia occurring in childhood that bears certain similarities to leukemia, but it is without the tendency to a fatal end.

Pathology.—Splenic enlargement is the most striking lesion. The organ is hard and dark red. The histologic examination shows a uniform hyperplasia, such as is found in splenic hypertrophy due to various conditions. The liver is usually enlarged, but presents normal appearances on section; slight enlargement of the lymphatic glands may occur, though never lymphomatous tumors.

Etiology.—Children under the age of four, and particularly during the second half year of life, are especially prone to this condition. It is equally common in the two sexes, and most often seen in rachitic infants, 16 to 20 cases collected by Monti and Berggrün having exhibited this etiologic factor. Hereditary syphilis, intestinal disturbances, and other diseases doubtless play a part in the etiology. The disease is rare.

Symptoms.—The onset is gradual. The child becomes pale, weak, and often emaciated, and *enlargement of the spleen* is the most striking feature. Sometimes this reaches such a grade that the left half of the abdomen is practically filled, variations in its size being observed from time to time. Hepatic enlargement is frequently present, but does not correspond to that of the spleen, and the lower border of the organ is found to be sharp instead of rounded, as is the case in leukemia. Gastro-intestinal disturbances may occur. Death may result from increasing weakness, peritonitis, or pneumonia.

Blood.—An examination of the blood will in many cases show an inordinate reduction in the number of red corpuscles. Nearly always the number is below 3,000,000. Degeneration of the red corpuscles, polychromatophilia, and poikilocytosis are seen. Large numbers of nucleated erythrocytes, especially normoblasts, may be found, and karyokinetic figures are frequently observed in the nuclei. The reduction in hemoglobin is often relatively greater than that in the number of erythro-

¹ Steinwald, *Jour. Amer. Med. Assoc.*, March 26, 1904, p. 828.

cytes. A marked increase in the number of leukocytes is one of the characteristics, the number ranging from 40,000 to over 100,000, and the proportion of the red to the white at times being as low as 12 to 1. Considerable fluctuations in the number of leukocytes may occur. Von Jacksch insisted that the different forms of leukocytes occur in their usual relative proportions. Hunter¹ speaks of three types, all different phases of the same condition—a secondary anemia: (1) the cases with leukopenia; (2) those with moderate leukocytosis, and (3) cases grouped as von Jacksch's splenic anemia.

Diagnosis.—The lesser grade of hepatic enlargement, and the character of the leukocytosis distinguish these cases from true leukemia. The evidence is in favor of its being a type of secondary anemia. In addition, I would say that the absence of hemorrhages, purpura, and lymphomatous enlargements, together with the existence of rickets, or a history of an impoverished state of the system, point to a non-leukemic affection.

Prognosis.—Under treatment most cases terminate favorably.

Treatment.—Hygienic measures together with the administration of remedies directed to the anemia constitute the treatment.

SPLenic ANEMIA.

Definition.—A condition described by H. C. Wood in 1871; it was looked upon by many authors as a splenic form of Hodgkin's disease. The present tendency is to regard it as a distinct variety of anemia.

Pathology.—Among pathologic characters, splenic enlargement is to be specially noted. It is an idiopathic enlargement of the spleen with anemia and without lymphatic involvement. Microscopically, there is hyperplasia of the spleen with atrophy of the pulp and hyaline degeneration of the Malpighian bodies. In other cases replacement of the normal structure by fibrous tissue and large endothelial cells occurs, with clear protoplasm containing several nuclei and giant cells among them.²

Etiology.—So-called splenic anemia is not rare in persons who have resided in malarial districts for a long period of time (although cases are recorded in which no previous history of malaria existed) and in rachitic persons. It is probably a process of chronic toxic nature.

Symptoms.—The affection is characterized by three stages:³ (1) The initial stage, which shows extreme anemia, with marked loss of power and muscular wasting, emaciation, however, being usually slight, notwithstanding.

(2) The second stage is characterized by progressive enlargement of, and pain in the region of, the spleen. Anemia is now profound, loss of strength extreme, and hematemesis common. Hemorrhages from other mucous membranes and, less often, of the skin, are also noted. The fever is apt to be hectic in type (ranging from 100° to 102° F.—37.6°–38.0° C.—and rarely even higher).

(3) The condition is that of progressive asthenia, ending in death.

In the last stage there may be cirrhosis of the liver, jaundice, and ascites (Banti's disease).

The Blood Characters.—The anemia is of the chlorotic type. The red cells are usually near the normal count (3,000,000 to 4,000,000), while the hemoglobin is greatly reduced (50 per cent. or lower). Poikilocytosis may exist. A leukopenia is usually present. The treatment is that of the graver

¹ *Lancet*, January 23, 1909.

² Osler, *Amer. Jour. Med. Sci.*, November, 1902.

³ S. West, in Allbutt's *System of Medicine*.

forms of anemia. Splenectomy is indicated by recurring hematemesis. Harris and Hertzog¹ report 14 recoveries in 19 cases, with 1 result not stated.

POLYCYTHEMIA WITH SPLENIC TUMOR.

This is a special complaint of obscure pathogenesis. The spleen is quite hard and usually enlarged. A cheesy tuberculosis has been noted, but this is not constant.

Etiology.—Certain writers regard changes in the bone-marrow as primary, leading to increased erythroblastic activity. The Hebrew race is markedly predisposed. A majority of the cases occur during middle life, and “the cases are about equally divided between the sexes” (Engelbach and Brown). “I regard it as probable that there is a form of primary polycythemia of unknown etiology, characterized principally by marked polyglobulism and other hemic features, cyanosis, headache, vertigo, and splenic enlargement, but it must be of rare occurrence.”² On the other hand, the majority of cases which have been reported have had a different etiologic pathology, circulatory stasis resulting from pressure of malignant tumors, valvular heart disease, and the like.

Symptoms.—According to Reckzeh,³ the first symptoms are vertigo, headache, mental apprehension, general weakness, and gastro-intestinal disturbance. In fully-developed cases marked cyanosis of the skin and mucous membranes, with dilatation of the veins and sometimes hemorrhages, are prominent features. The spleen may extend downward to the level of the umbilicus. The characteristic blood-findings are an enormous increase of the hemoglobin, rarely to 150 per cent., and a high erythrocyte count, the estimation ranging from 7,000,000 to 12,000,000 in some cases. The leukocytes vary as to number, but often about nominal figures are found.

Geisböck describes a second form, or *polycythemia hypertonica* (erythrocytosis), in which the blood-pressure is, as a rule, quite high. The majority of cases are associated with arteriosclerosis and nephritis, but not all. Neither is viscosity of the blood responsible for the rise of arterial pressure. The changes in the bone-marrow, in one case at least, were identical with those of Vaquez's disease. In this variety the spleen is not enlarged, but otherwise the symptomatology and treatment are the same as in polycythemia with splenic enlargement.

The *course* is exceedingly chronic, and the *prognosis* unfavorable.

The *treatment* is by arsenic, quinin, and an iron-free vegetable diet and a carefully regulated mode of life. The iodids have been advised in order to decrease the viscosity of the blood. The cerebral symptoms have been benefited by the nitrites. Splenectomy may be indicated.

DISEASES OF THE DUCTLESS GLANDS.

DISEASE OF THE SUPRARENAL CAPSULES.

ADDISON'S DISEASE.

Definition.—A constitutional disease, characterized by a degeneration of the suprarenal capsules or semilunar ganglia, a bronzed or pigmented skin, great bodily and mental asthenia, feeble circulation, and gastro-intestinal irritability.

¹ *Annals of Surgery*, July, 1901.

² *Amer. Jour. Med. Sci.*, June, 1907, by the writer.

³ *Zeit. f. klin. Med.*, vol. lvii., Nos. 3 and 4.

This affection is named in honor of its discoverer, Thomas Addison of Guy's Hospital, London, who first described it in a monograph published in 1855, entitled "The Constitutional and Local Effects of Disease of the Suprarenal Capsules."

Pathology.—Addison emphasized the fact that while the suprarenal bodies were affected with a fibro-caseous alteration in many cases, the anatomic changes were by no means always the same. Both suprarenal capsules are usually diseased at the same time. Tuberculosis is the commonest condition, and is often associated with tuberculous lesions in other parts of the body, as in the lungs, bones, and other glands. Rarely, it seems to be primary, no other evidences of tuberculous infiltration being found. The capsules are enlarged, firm in places, and nodulated on the surface, owing to the caseous masses surrounded by fibrous tissue. Sometimes there is marked cicatricial contraction of the adrenals, and the adjacent structures may be found matted together with the capsules. *Microscopic examination* shows a reticulum of connective tissue surrounding a soft, cheesy, granular, and fatty detritus, lymphoid cells, and some giant-cells. Other morbid, non-tuberculous processes in the adrenals are atrophy of one or both glands from interstitial cirrhosis, carcinoma or sarcoma, and chronic inflammation.

Especial attention has recently been given to the condition of the *solar plexus* and *semilunar ganglia* of the abdominal sympathetic, and implication of these nervous structures by compression, cicatricial contraction, entangled in the cicatricial tissue surrounding the suprarenal bodies, or by chronic inflammation, is not infrequently discovered, together with a degeneration and deep pigmentation of the semilunar ganglion-cells.

Enlargement of the solitary and agminated follicles of the intestine, and slight enlargement and some softening of the spleen are noted at times; parenchymatous or fatty degeneration of the heart, liver, and kidneys has also been noted in some instances. The thymus gland may be found to have remained normal, or even to have enlarged, perhaps. The deposition of pigment is in the same anatomic elements as in the negro—in the lower layers of the rete Malpighii.

The pathologic connection between the symptomatic phenomena of Addison's disease and the anatomic lesions has not been made out. The experimental evidence regarding the functions of the adrenals is imperfect; but it seems quite probable that some essential "internal secretion," influencing the normal metabolism of the skin and muscles, is diminished or absent in Addison's disease. On the contrary, cases exhibiting the clinical phenomena of this affection have occurred in which no suprarenal morbid processes could be found *post mortem*. Again, marked changes have been observed in these glands, while during life no symptoms of the disease had been noted. Hence, it is maintained by some that the abdominal sympathetic nerves and ganglia are directly concerned in producing the clinical manifestations, either by an independent morbid process or by extension from some adjacent organ. Others hold that both the adrenals and the sympathetic ganglia are the seat of pathologic changes. The data are not sufficient, however, to determine whether the principal involvement is nervous or secretory.

Etiology.—This is obscure. It has been held that some infection of the blood from without precedes the suprarenal and nervous lesions of Addison's disease. A *tuberculous* diathesis or infection has also been

emphasized by some investigators, and Fleming and Miller¹ have reported a family with probable Addison's disease. A history of *injury* to the trunk has been noted in several cases. The disease is more common in Europe than in America, though it is rare everywhere. Analysis of 183 cases showed 119 males and 64 females (Greenhow). While the disease may affect all ages (it may even be congenital), it is usually found in early or middle life—between fifteen and forty years of age. That Addison's disease is due either to a general neurosis or to disturbed hematopoiesis is merely hypothetical.

Symptoms.—While it does happen not seldom that tuberculosis or carcinoma affects the adrenals, the purest and most typical symptoms of Addison's disease are apparently primary in their development, and not those that usually attend the course of the former diseases.

Cutaneous Symptoms.—The gradual pigmentation of the *skin* of various parts of the body may be one of the first evidences of the affection. This pigmentation may have either a dusky-yellow, bronze or yellowish-brown, olive, deep or greenish-brown, or even black color. Although sometimes diffuse, the discoloration is not uniform over all parts of the body, but commences earlier, and becomes deeper especially on the exposed parts and where the normal pigmentation is marked, as the face, neck, backs of the hands, the axillæ, abdomen, groins, genital regions, and the areolæ of the nipples. Pigment-spots, often somewhat bluish in color, are also found on the *mucous membranes* of the mouth, lips, conjunctiva, and vagina. On the lips the discoloration takes the form of a dark streak, running lengthwise, near the junction of the skin and mucous membrane; or brownish patches or streaks corresponding to the points of pressure by the teeth may be noticed. Irregular stains with ill-defined borders may also be shown on the skin, corresponding to the lines of pressure exerted by garments, strings, suspenders, garters, etc. (Greenhow). White patches of *leukoderma* may be seen here and there, in marked contrast to the pigment-deposits. The "white line," produced by drawing the finger lightly over the skin of the abdomen, is characteristic.

General Symptoms.—The constitutional symptoms may exist in a slight degree before the pigmentation first attracts the patient's attention. There is gradual and progressive *asthenia* without apparent cause, great lassitude and loss of physical and mental energy, breathlessness, headache, dizziness, tinnitus aurium, sighing, and fatigue. The *blood-examination* shows a moderate reduction of the erythrocytes and hemoglobin, rarely becoming marked. There is no leukocytosis and often a leukopenia. The fat, particularly of the abdomen, may be well preserved.

Circulatory Symptoms.—The *heart's action* is weak and the pulse small and feeble; attacks of faintness and palpitation on exertion are common, as are functional murmurs and coldness and clamminess of the extremities. The blood pressure is greatly reduced before death (Turner).

Gastro-intestinal symptoms are usually prominent. There is a loss of appetite, and nausea and vomiting may occur early and either be paroxysmal or persistent. The *tongue* may be clean, and the gastric disturbances do not seem to follow errors in diet. *Diarrhea* may be troublesome in the latter stage, and is often associated with intractable

¹ *Brit. Med. Jour.*, April 28, 1900.

vomiting. *Neuralgic attacks* of either sharp or dull, aching pain are referred to the epigastric, hypochondriac,* and lumbar regions in about one-third of the cases. The *mind* is usually clear until near the last, but mental weariness is constant, and, as the latter stages of the disease come on, the patient often lies in a somnolent, semi-comatose state. The physiognomy expresses fatigue, dejection, and apathy; the speech becomes slow and incoherent, and in many cases the patient passes into delirium. *Prostration* is profound, the weakness being disproportionate to the general condition.

Renal Symptoms.—Polyuria is sometimes evident, but albumin is seldom present. The amount of indican is increased, as it is in the urine of all of the cachectic diseases associated with destruction of albuminoids. There is usually a diminished excretion of urea, but urobilin and uromelanin may be present in abnormal quantity. Tubercle bacilli may be found in the sputum.

Diagnosis.—The principal error in diagnosis is in the assumption that the case is one of Addison's disease, simply from the presence of patches of pigmented skin. Other conditions in which the discoloration may simulate that of Addison's disease are the following: (1) Carcinomatous and tuberculous disease, particularly when seated in the abdomen and when involving the peritoneum; (2) Hepatic disease, such as the cirrhosis of diabetes, protracted jaundice, chronic congestion, and lithemia ("liver-spots"); (3) Pregnancy, and uterine disease, in which the patchy discolorations (chloasmata) appear principally upon the face; (4) Irritation of lice and dirt and exposure, as in the case of tramps and vagrants ("vagabond's disease"); (5) Tinea versicolor; (6) Melanotic sarcoma; (7) Exophthalmic goiter; (8) Post-eruptive staining of syphilitic eruptions; (9) The administration of silver nitrate for a long time (argyria); (10) Marked brunette complexions and racial admixture.

When the pigmentation is scanty, of course the diagnosis is more difficult; but in all cases of pigmentation in which other causes may be excluded the progressive asthenia, unaccountable vomiting and diarrhea, easily compressible pulse, great bodily weakness, mental hebetude, and lumbar and epigastric pain render the diagnosis of morbus Addisonii, or *malasma suprarenale*, justifiable. The bronzing of the skin may precede as well as follow the constitutional symptoms.

In the negro the diagnosis of this affection is extremely difficult, both on account of the naturally dark skin and because of the dark discolorations of the oral mucous membrane, found even in health.

Prognosis.—The course of Addison's disease is almost always chronic, though cases have been reported occasionally in which the onset has been sudden, with febrile phenomena and a comparatively acute course of a few months, or weeks even. Usually the disease lasts about one year, although some cases may continue over five or even ten years. Temporary remissions may be observed, but death is inevitable in by far the majority of instances. The termination is gradual, and by profound asthenia, or sometimes by coma, delirium, or convulsions (epileptiform).

Treatment.—The hygienic and medicinal treatment must have the same objects in view as in the other grave cachectic diseases, and is both sustentative and symptomatic. As quiet a life as possible should be strictly enjoined, owing to the dangers of sudden and fatal syncope. Rest in bed is necessary in moderate and advanced cases during a part

of the day for the former and constantly for the latter. The diet should be restricted to light nutritive, concentrated, and easily assimilable food. Carbohydrates in the diet have been found to diminish the adynamia. An absolute milk diet may be necessary in some cases.

Iron and arsenic may be administered in the anemic cases, and strychnin, guaiacol carbonate, phosphorus, and the nuclein preparations may also be given, along with bitter tonics. Bismuth and salol may be of great service in controlling the diarrhea that often occurs. The nausea and vomiting may be relieved by unfermented grape-juice, albumin-water, champagne, cracked ice, cerium oxalate, creasote, and the like. Electricity is often a valuable adjunct in the treatment of the muscular weakness and nervous exhaustion, and even in reducing the pigmentation.

It seems quite probable that the administration of the extract of suprarenal capsules will prove to be of considerable value in causing marked improvement, if not a permanent cure, in a certain percentage of cases. In one instance mentioned by Osler, in which a glycerin extract of a pig's suprarenal was given at first in doses of half a glass three times a day, improvement was noted in the temperature, pulse, weight, and physical and mental vigor from the first week of the treatment, which was continued for three months and a half. Eight months after the treatment was begun the patient appeared to be well and strong, and attended to business; the pigmentation, however, was not removed. In a recent case of my own this remedy produced like results. Robin mentions a case treated by the administration of suprarenal gland that has shown persistent good health for three years. For the present, however, too positive a value should not be attributed to the suprarenal extract, and results contrary to the above are to be found in the literature. Grafting of the gland, inserting only small fragments, has been proposed.

DISEASES OF THE THYROID GLAND.

THYROIDITIS.

Definition.—Acute inflammation of the thyroid gland. The gland may either have been previously healthy or the seat of a goitrous enlargement; when inflammation attacks previously diseased or enlarged thyroid tissue the term *strumitis* is often used.

Pathology.—The gland is swollen, boggy, and the seat of abscesses; the numerous blood-vessels are engorged; and hemorrhages, thrombi, and areas of tissue-necrosis are found.

Etiology.—Thyroiditis is seldom primary in origin. It may be caused by traumatism, but usually it is secondary to one of the infectious diseases (small-pox, typhus, typhoid fever, malaria). Rheumatism has also been given as a cause. Hemorrhages into the substance of a goiter, whether apoplectic or traumatic, may predispose to a strumitis that may be excited by the introduction of streptococci by an unclean needle, etc. Repeated congestions of the thyroid or a simple acute congestion may dispose to thyroiditis.

Symptoms.—There are *fever, pain, swelling, and suppuration* in one or the other lobe of the gland. *Venous obstruction* may be serious and gives rise to vertigo, headache, cyanosis, and epistaxis; and compression of the windpipe by the great swelling may cause death before

the abscess bursts. Resolution occurs infrequently, especially in the "strumous" cases. Indeed, the symptoms of a strumitis are usually more severe, owing to the greater size of the thyroid, a tendency to metastasis, and to the burrowing of pus into adjacent tissues leading to perforation and rupture of the abscess into the trachea or esophagus.

Diagnosis.—Thyroiditis must be differentiated from the *laryngeal perichondritis* that is also seen in the course of infectious diseases, as typhoid fever and small-pox. The higher and more median position and the smaller swelling of laryngo-chondritis are distinctive points.

Prognosis.—The outcome is usually favorable in all cases in which spontaneous rupture occurs externally or when evacuation of the pus is effected. Strumitis runs a less favorable course.

Treatment.—This is antiphlogistic and surgical. The pus must be evacuated, and tracheotomy or thyroidectomy may become necessary.

GOITER.

(*Bronchocele.*)

Definition.—A chronic hypertrophy and hyperplasia of a portion or the whole of the thyroid gland. It is of obscure origin, and is subject to various degenerative changes.

Pathology.—Several different varieties are described. In the *simple hypertrophic* or *parenchymatous* form there is a hyperplasia of all the original tissue-elements. The *follicular* form shows an increase of the true glandular elements alone.

Fibrous goiter is that variety in which the interstitial tissue or stroma is increased out of all proportion to the hyperplasia of the follicles. This variety of goiter may have an inflammatory origin (thyroiditis). In old cases marked sclerosis may be assumed. There is a *vascular* variety, in which the blood-vessels are enormously dilated. More commonly the veins are affected, but in the aneurysmal variety the arteries are chiefly involved. The intense venous variety of vascular goiter has been denominated "cancerous tumor of the thyroid," and the whole gland may in such cases be quite elastic and like spongy erectile tissue. Follicular hyperplasia is often associated with vascular enlargement.

The special varieties of goiter due to degenerative changes are the *cystic*, *amyloid*, *colloid*, and *calcareous*, and of these the first named is the most common. It consists in the development in a large goiter of one or more large or small cysts filled with different kinds of fluid of varying consistency. Sometimes the liquid is colloid or mucinous in nature, and contains the residue of hemorrhages (cholesterin and fatty products). Amyloid changes affect principally the vessels; colloid changes are also frequent, while calcareous infiltration is seen in old fibrous goiters. Inflammation and suppuration of the goitrous gland may ensue.

Etiology.—Goiter may occur anywhere sporadically. Endemically and in its worst forms it occurs in the mountainous districts of Europe, Asia, Mexico, and South America, particularly in the Alps, Pyrenees, and Andes. It has also appeared in certain limestone regions, such as New England and Ontario, Canada, where the *habitual use of limestone-water* for drinking purposes seems to induce the disease. *Heredity* undoubtedly plays a part in its causation, certain children having been born with goiter. Occasionally it has become epidemic in certain sections of the goitrous districts in Europe where military garrisons have

been stationed, thus indicating the possibility of some infectious influence. Women are more liable to goiter than men, and it is more common to find it after ten or twenty years of age. It has been alleged that pregnancy also influences the development of this condition.

Symptoms.—The enlarged thyroid is readily *recognized* and *felt*, though the patient may complain of nothing but the disfigurement, except when the tumor is of sufficient size to cause symptoms of compression. The goiter develops very gradually, and may vary in dimensions from the merest perceptible enlargement to a growth that overhangs the chest and greatly hinders the movements of the head. It may or may not be uniform in its development, and is often more enlarged on the right side and in front than on the left side. It is not infrequently observed to increase in size with each succeeding pregnancy and during or after each menstrual flux.

The tumor is *painless*, is not adherent to the overlying skin or to any of the neighboring bones, and rises and falls during the act of swallowing, moving with the larynx. The *veins* covering it are swollen and prominent. It interferes with respiration oftener than with deglutition, causing dyspnea; alteration or loss of the voice may also ensue. Displacement and distortion of the trachea, the vessels, and other cervical tissues may be produced. Large *pendulous growths* usually cause less serious discomfort than the small encircling tumors that extend downward into the thorax. Headache, somnolence, and marked cerebral symptoms, such as tetany and convulsions, have been described.

The *general health* or nutrition seldom fails unless inflammation and suppuration (strumitis) attack the goiter during the course of some infectious disease, as not infrequently happens, or in cases in which the thyroid function is abolished, leading to the profound nutritional and cerebral disorders of cretinism in children or myxedema in adults.

Dettrich and Osler have each reported an instance of a goitrous growth affecting aberrant portions of thyroid found in the upper region of the pleural cavity, one on the right and one on the left side.

Sudden death may ensue in a few cases, either from pressure on the vagi, or from a severe hemorrhage.

Auscultation often reveals a loud blowing murmur, especially marked in the vascular bronchoceles. *Palpation* over the tumor often shows the bossellated surface present in cystic goiter; fluctuation may also be detected in such cases, as well as over the abscess of a strumitis.

Diagnosis.—Goiter is easily differentiated from other enlargements. The constant location and the character and course of growth of the bronchocele are distinctive. If both lobes of the thyroid are affected, making a symmetric swelling, the diagnosis is almost assured. Bronchocele is not easily confounded with other cervical tumors, such as *lymphadenoma*, *glandular tuberculosis*, *carcinoma* or *abscess of the thyroid*, or sebaceous cysts. A characteristic feature of tumors of the thyroid is their vertical movement during the act of deglutition.

Prognosis.—This is guardedly favorable as to life, but unfavorable as to cure. The course is chronic.

Treatment.—Prophylaxis should be practised in goitrous districts by the drinking of boiled water only, and removal to a non-goitrous region is advisable. The majority of drugs recommended for internal and external use have been proved valueless, though in the parenchymatous

and follicular forms potassium iodid by the mouth and the vigorous and methodic use of iodin over the tumor have been much lauded. Mercurial ointment—the red or biniodid especially—has also been recommended for local application. Ergot or belladonna in progressively increasing doses may do good in vascular goiters. The younger and softer goiters may also be benefited by electrolysis, needles attached to the negative pole being inserted into the substance of the tumor while a large sponge or clay positive electrode is placed in the vicinity.

In the older, fibrous, and degenerated goiters surgical treatment alone may be of service. Injections of iodin, tapping of cysts, incisions of the isthmus, and ligature of the thyroid arteries have been practised among the lesser operations. Thyroidectomy, or a partial extirpation of the thyroid, is the radical and final operation. Recently, the fresh, chopped thyroid gland of the sheep, spread on bread, was given in 20 cases of follicular and parenchymatous goiter with gratifying results. Complete recovery, in an anatomical sense, however, was realized in two cases only. The administration of thyroid has transformed several cases of simple goiter into those of the exophthalmic type.

EXOPHTHALMIC GOITER.

(*Graves' Disease; Basedow's Disease.*)

Definition and Nature.—Although the view cannot be unreservedly accepted, exophthalmic goiter is probably of thyroid origin and is dependent upon an abnormal action (or over-action) of the thyroid gland; it is characterized clinically by tachycardia, tremors, enlarged thyroid, and exophthalmos. Among other leading theories the following may be briefly stated: (1) that it is due to disturbed innervation (Buschan); (2) that the seat of the disease resides in the medulla oblongata; (3) that it is an affection of the sympathetic nerves; and (4) that it is a disease of the central nervous system associated with a chronic intoxication.

The theory held by Möbius, that exophthalmic goiter is attributable primarily to a disturbance of the function of the thyroid ("hyperthyroidation"), a condition directly opposed to the lack of thyroid function, as in myxedema, is amply supported by clinical evidence, the complex symptom-group of the former being directly antagonistic to that of the latter disease. Thyroid-feeding, moreover, while it sometimes causes parenchymatous goiters to disappear rapidly, usually aggravates the symptoms of Basedow's disease. Regarding the *pathologic changes* in the thyroid little is known. Brissaud¹ found in 25 cases changes in the thyroid, and, although the glands showed no changes peculiar to this disease, yet quantitatively the lesions were always such as to make "hyperthyroidation" possible. A parenchyma increase, in direct proportion to the intensity of the symptoms, occurs (L. B. Wilson). Persistence, and sometimes hypertrophy, of the thymus gland is common. Hector MacKenzie² believes that atrophy of the parathyroids may be the cause of some of the more serious symptoms. Muscular changes, probably resulting from toxemia, explain the profound muscular weakness (Askanaazy). Jaunin³ and Gautier⁴ contend that chronic iodism and exophthalmic goiter are practically the same condition. Minor⁵ affirms that the disease may be due to gastro-intestinal auto-intoxication.

³ *Rev. méd. de la Suisse rom.*, No. 5, p. 301, 1899.

⁴ *Med. Rec.*, Dec. 2, 1899.

⁵ *Ibid.*

Etiology.—It is more common in women than in men. A table of 200 cases showed 161 females and 39 males (Eshner); and, although it has been met with at both extremes of life, it is seen usually in adults. The influence of heredity is undoubted, and several members of a family may suffer, persons that possess a sensitive nervous organization being especially prone to the disease.

Among direct causes are emotional disturbance, worry, severe acute disease (noted in two of my cases), and prolonged mental or physical strain.

The disease may also occur as a secondary complication in the course of simple goiter, affections of the nose, and pregnancy; this variety, however, is to be distinguished from the primary or essential form.

Symptoms.—The development of the characteristic symptoms is generally *gradual*, though it may rarely be *rapid*. In the so-called abortive form the symptoms arise somewhat rapidly, but early subside.

In *acute* Basedow's disease the symptoms consist of an excessively rapid action of the heart, incessant vomiting, purging, and marked exophthalmos, with or without pronounced cerebral symptoms. J. H. Lloyd's case proved fatal after an illness of three days.

In the *chronic* form heart-hurry is almost constantly a conspicuous early symptom, and not seldom have I found that it recedes for a long period of time the appearance of the remaining characteristic features (enlargement of the thyroid, exophthalmos, and tremor). The pulse remains at or over 100 beats per minute, and upon unusual exertion or excitement the heart's action becomes violent and irregular, the pulse even reaching 160 or over. Palpitation, often with breathlessness, is a distressing symptom.

Cardiac Physical Signs.—*Inspection* reveals a forcible impulse that is not displaced, though late in the affection it may be much extended in superficial area. The carotids and the abdominal aorta beat violently, and the capillaries and veins of the hands may also pulsate visibly. *Palpation* detects an increased force of the cardiac impulse. The area of *percussion-dulness* may be somewhat increased, as hypertrophy and secondary dilatation supervene. On *auscultation*, blowing murmurs over the heart and great vessels, as well as an increased accentuation of the valvular sounds, may be audible for some distance from the patient. Distinct *bruits* may be heard over the base and manubrium.

Exophthalmos.—Protrusion of the eyeballs is usually present. The degree of exophthalmos varies greatly from time to time in the same case—a fact that points to an increased amount of blood or lymph in the orbit as its cause. In advanced cases permanent prominence of the balls may be attributable to augmentation of the orbital adipose tissue. On closing the eyes a rim of white is visible above and below the cornea; this and Graefe's sign, immobility of the upper lid when the eye is turned downward, are two symptoms of great diagnostic importance. Möbius has called attention to the inability to converge the eyes upon near objects; and Stellwag, to an apparent separation of the eyelids, due to spasm or retraction of the upper lid. The pupils and the vision are unaffected, while the patient winks less often than in health. Slight momentary retraction of the upper eyelids occurs on gazing at some object if the latter be moved rapidly up and down (Kocher). Abnormalities are rarely presented by the optic nerves, and ulceration of the cornea may supervene. The retinal arteries pulsate.

Thyroid enlargement may either accompany or follow the exophthalmos, and has for its cause the great dilatation of the vessels, particularly of the arteries. The enlargement is usually moderate, and may be general or partial, the size of the gland exhibiting sudden variations, since it is dependent upon the circulatory disturbance. *Inspection* may also show visible pulsation; *palpation* feels a thrill, and Kocher states that an important sign is tenderness of the thyroid. *Auscultation* renders audible a double systolic murmur. The latter sign is probably present in most instances, though not constantly.

Nervous Symptoms.—*Muscular tremors* form an early symptom; they are involuntary, and fine in character, numbering about eight to the second (Osler). The characteristic features of *neurasthenia* appear and gradually increase in intensity. *Mental disturbances*, particularly marked depression or great excitability, are common, and even mania (which may prove speedily fatal) or melancholia may be observed.

Cutaneous Symptoms.—The *temperature* may at intervals be moderately elevated, and this symptom may be associated with profuse sweatings. Among other cutaneous phenomena, though these are for the greater part occasional, are *pigmentation* (which, in the case of a physician whom I recently saw suffering from Basedow's disease, was as pronounced as in typical Addison's disease), *scleroderma*, *urticaria*, *pruritus*, and *circumscribed solid edema*. In the advanced stage *malleolar edema* sets in and may become general. A marked diminution in the cutaneous resistance to the electric current has been noted by Charcot. The forehead is not wrinkled as in health.

General Symptoms.—Muscular weakness, either local or general, is pronounced; the patient becomes anemic and is at last extremely emaciated. An early sign is *leukopenia*, the neutrophiles being much reduced, while the lymphocytes are twice the normal figure. *Vomiting* and *purging* may appear at different times and assume great gravity, and in some cases *hemorrhages* (epistaxis, hemoptysis, hematemesis) tend to supervene. *Albuminuria* and an increased amount of urine, with glycosuria, are among the commoner complications. Louise Bryson has maintained that diminution in the chest-expansion is a characteristic sign of exophthalmic goiter; and Patrick,¹ who examined 40 cases, found that there was an average diminution, but believed it to be proportionate to the amount of muscular weakness. Rarely a *myxedematous* condition is associated; probably the disease is also remotely related to scleroderma.

Diagnosis.—The diagnosis of Graves's disease may be made when tachycardia or delirium cordis and fine, general muscular tremors are present. Exophthalmos and enlargement of the thyroid are often late-appearing symptoms, and are as often temporarily lacking even in fully-developed cases. Rarely, either or both of these signs may be permanently absent. On the other hand, in a few cases exophthalmos is the sole characteristic feature for a long time, though it is eventually followed by an unmistakable symptom-group. Dernini emphasizes temporary increase in the clinical diameters of the heart after exertion, as a diagnostic feature. Parenchymatous goiter presents a non-pulsating tumor.

Course and Prognosis.—The chronic form of the disease endures, as a rule, for a few years. A gradual subsidence of the cardinal symptoms for a long period has been noted, and in such cases complete recovery

¹ *Deutsche med. Woch.*, Dec. 20, 1894.

ery may be claimed. In fully-developed cases the prognosis formerly was almost hopeless, but since the introduction of the operative treatment many cases have been greatly benefited, and others cured.

Treatment.—This is (a) *Hygienic*, (b) *Medicinal*, and (c) *Operative*.

(a) **Hygienic.**—The environment, both physical and mental, should be made as favorable as possible. A change of climate, and especially moderate elevation, in cases not too far advanced, bring about beneficial results. Such elevation (3250 feet) produces a sedative effect upon the nervous state that reacts most favorably upon the circulatory organs, while the purity and tonic quality of the air have a general strengthening and restorative effect (Yeo). Among other promising measures may be mentioned the wet-pack, methodical hydrotherapy with massage, and a continuous galvanic current. The electric treatment should be given a thorough trial over three or four months (Osler). The local use of an ice-bag to the precordium has acted admirably in reducing the heart-hurry in a few cases of my own. Rest in bed for a few weeks at a time, at intervals, is often followed by improvement. The diet should be carefully supervised, according to the indications of special cases.

(b) **Medicinal Treatment.**—This is probably secondary to the hygienic and operative measures. In two cases of my own, however, recovery followed the persistent use, for about six months, of the following prescription :

M. et ft. capsulæ No. xxiv.

Sig. One t. i. d. after meals.

In 2 other cases (one, a trained nurse) the use of sodium salicylate (gr. x-0.648—four times a day) was followed by almost total relief. L. Webster Fox also warmly advocates the latter remedy in this affection. Trachewsky, in Kocher's clinic, found that sodium glycerophosphate (gr. xx—1.296—three or four times a day), had the effect of diminishing the size of the enlarged thyroid glands, and Starr¹ has also found this remedy of great service in several cases. Other therapeutic agents that have been extensively employed, but with doubtful advantage, are aconite, veratrum viride, and belladonna. From all of the clinical testimony at hand I feel convinced that thyroid-feeding is contraindicated in the treatment of Basedow's disease, unless a myxedematous condition be associated, when it may prove efficient. S. Solis-Cohen and others have used extract of suprarenal gland with good results. W. G. Thompson holds that the exacerbations, which are of a toxic character, may be completely checked by the cytotoxic serum of Rogers, prepared from the diseased human glands through animal inoculation. Krumholz² holds that serum of thyroidectomized animals is the most valuable drug yet offered. Anti-thyroid preparations, such as thyroidotoxin, give promise of good results. Möbius's thyroïdin (a preparation of the blood of sheep in which the thyroid gland has been removed some time previously) has given good results. The dose is from 2 to 12 drops daily, given for a period of twenty days. Shattuck advises neutral bromid of quinin, and F. Bill-

¹ *Medical News*, April 18, 1896.

² *Illinois Medical Journal*, March, 1910.

ings, the hydrobromid (gr. v—.324 four times daily), for its vasoconstricting effects. Lecithin is found useful when digestion is undisturbed, but "it fails without the assistance of a milk diet" (Berkley).

(c) **Operative Treatment.**—Starr¹ has collected 190 cases in which some form of operation was performed. Of these, 74 are reported as completely cured, many of them having been watched two to four years before the result was published; 45 of the cases were improved, and 23 died immediately after operation. The symptoms preceding the fatal result are sudden hyperpyrexia, with rapid pulse, nervous distress, sweating, cardiac failure, and collapse. The statistics of Kinnicutt and of Abram² (particularly the latter) show less encouraging results from operation. It is to be remembered that under the most favorable circumstances a complete cure will not be attained immediately. In cases unimproved by non-operative treatment in a reasonable time, partial thyroidectomy may also be advised. Bilateral resection of the sympathetic nerve has been done by Schwartz and others with marked benefit. Rehu³ presents a statistical report of 32 resections of the sympathetic: 31.1 per cent. were cured; 50 per cent. improved, 12.5 per cent. were unimproved, and 9.5 per cent. proved fatal. F. Hartley⁴ states that, compared with sympathectomy, partial thyroidectomy yields better results, both as regards mortality and cures. Crile claims benefits from ligation of the thyroid artery, which breaks the nerve supply between the brain and the thyroid gland. Kuh⁵ employed the serum-treatment in 11 cases with marked improvement in the subjective condition of the patients. Pfahler noted decided improvement from the x-ray treatment in about 75 per cent. of 51 cases.

MYXEDEMA.

(*Sporadic Cretinism.*)

Definition.—A nutritional disorder, consequent upon atrophy and loss of function of the thyroid gland, characterized by a myxedematous infiltration of the subcutaneous tissue and a cretinoid cachexia.

Three varieties occur, as follows: (1) True myxedema; (2) Cretinism (the absence of thyroid function—congenital, or lost during childhood); (3) Operative myxedema, due to total removal of the glands for surgical reasons or in experiments upon lower animals.

Nature of Myxedema Proper of Adults.—Charcot, who gave the name of *cachexie pachydermique* to this disease, believed it to be of tropho-neurotic origin. Atrophy of the thyroid is pretty constantly present, and the gland may either be converted into a small fibrous mass or be entirely absent, so that the causal relation between myxedema and functional and structural alterations of the thyroid seems to be conclusive. Moreover, the therapeutic test of improvement under the administration of thyroid extract sustains this view. It is probable that the active thyroid supplies some essential secretion which maintains normal metabolism, though this product has not been isolated. Its existence being inferred, however, it has been called *thyroidin*.⁶ Ponfick has

¹ *Loc. cit.*

⁴ *Annals of Surgery*, July, 1905.

⁵ *Medicine*, September, 1905.

⁶ The term "thyroidin" has also been given to a substance possessing specific therapeutic activities that has been obtained from the thyroid gland of the sheep.

pointed out that the hypophysis sometimes shows changes resembling those in the thyroid gland. The fact that in a good many cases of myxedema a considerable portion of the thyroid gland is unaltered and partly capable of functioning arouses a suspicion that the hypophysis may share in the production of this disease. The thymus has been found to be enlarged in myxedema.

Etiology.—The thyroid was destroyed by *actinomycosis* in a case of myxedema reported recently. Myxedema may also be secondary to *exophthalmic goiter*, but it is then, as in the case of a simple acute goiter, only a transient condition. Women are much more frequently affected than men, and a neurotic condition may precede some cases. The disease may affect several members of a family, and hereditary transmission through the mother has been observed. Sisters may suffer, one from myxedema and the other from *exophthalmic goiter*. Döderlein¹ reports the case of a child born with typical myxedema. Pregnancy may cause a disappearance of the myxedematous symptoms (Osler). The symptoms may reappear after delivery.

Symptoms.—The myxedematous condition is most plainly noted in the *face*, the skin being swollen, but inelastic, rough, dry, and firm. The lines of facial expression are obliterated, and the features are broad, coarse, immobile, and bulky. The *physiognomy* is stupid, dull, and phlegmatic, and simulates imbecility. The *hair* falls out, owing to deficient nutrition; and the general bulk of the body is markedly increased. Pressure does not produce *pitting*, as in true edema. According to Ord, the local tumefaction of the skin and subcutaneous tissue is most frequently prominent in the supraclavicular regions. The *mucous membranes* are also infiltrated, and the teeth may become loosened. The tongue, lips, and nose are thickened, and the voice is monotonous, slow, and has a "leathery tone," "with curious nasal explosions at short intervals during speaking." Bodily movements are slow, and the gait is uncertain on account of disturbed coördination.

Nervous Symptoms.—There is obvious retardation of psychomotor action. Mental perception and thought are also slow, and the memory, while retentive, is slow to respond. Not infrequently there may be considerable irritability, or hebetude alternating with sudden excitability. The patient may become suspicious, and later is subject to delusions and hallucinations; or the apathy may pass into a melancholia, ending at last in dementia. Ord mentions "the aggravation of all symptoms during low climatic temperatures;" and "among the minor or accessory signs may be quoted abnormal subjective sensations, belonging particularly to taste and smell; occipital headache; marked alterations of temper; and a curious persistence of thought and action, overriding all attempts at interruption by friends or observers."

The *temperature* in myxedema is usually more or less subnormal. Albumin and sugar are occasionally found in the urine, but the quantity of nitrogen excreted is small, owing to the diminished metabolism of proteids. *Hemorrhages* from the nose, gums, and bowels may occur. *Ascites* may be present in some cases, and may simulate ovarian tumor. The thyroid is not palpable, partly because of its atrophy, and partly because of the thickened myxedematous tissues of the neck.

The **diagnosis** is not difficult if one bears in mind the character-

¹ Norsk Magazin for Lægevidenskaben, Christiana, July 4, 1910.

istic manifestations described above. Myxedema could hardly be mistaken for acute or chronic nephritis in the absence of pitting, etc., as some have supposed. Chapman¹ mentions a solid appearance of the conjunctiva as an early sign of diagnostic value.

The **prognosis** is guardedly favorable in a majority of the cases since the introduction in the treatment of thyroid-feeding. The course of the disease is slow, however, often lasting from five to fifteen years, and death from intercurrent disease is not uncommon.

Treatment.—Until the advent of thyroid-feeding the treatment of myxedema was palliative, and usually unsuccessful.

A warm and equable climate is very desirable, owing to the sub-normal temperature from which the patients frequently suffer. The various warm baths—as the Turkish, Russian, and electric—should be employed for the same reason. Pilocarpin has been recommended, and strychnin and arsenic have been administered for their tonic effect.

Since the brilliant results obtained by Murray, however, the internal use of the thyroid gland of sheep or calves has come into a well-deserved favor in the treatment of all cases of myxedema, whether of the so-called true form, of sporadic cretinism, or of the cachexia strumipriva. The gland may be given raw or cooked, in the form of the glycerin extract, or in the powdered extract; the last named is sometimes put into tabloid form. If cooked, the gland should be only partially “done.” The fresh thyroid is minced and often spread on bread, and from one-quarter to one-half a gland may be taken daily.

The glycerin extract is readily made. “Several dozens of thyroids of young sheep or calves are carefully separated from the connective tissue, cut into small pieces about the size of a bean, and then put into a jar and covered with glycerin of the best quality, allowing 2 c.cm. of glycerin for each lobe of the thyroid used. The mixture is permitted to stand for twenty-four or thirty-six hours, and is then squeezed through a cloth, so as to get out as much liquid as possible. Of this, 2 c.cm., corresponding to about half a gland, may be given at a dose. If used for hypodermic injection, to a dram (4.0) of the glycerin extract is added half a dram (2.0) of a 1 per cent. solution of carbolic acid in distilled water, of which mixture from 10 to 15 minims (0.66–1.0) may be injected three or four times a week.”²

It is safest—for reasons that will be pointed out below—to begin with quite small doses, and gradually increase, especially if there is much gastric irritation. Not more than 5 minims (0.333) of the glycerin extract should be given at the start. This dose may be increased gradually until 15 or 20 minims (1.0–1.33) are taken three times daily. From 3 to 5 grains (0.194–0.324) of the powdered gland or tabloid form will be a safe commencing dose in adult myxedema: a caution, however, is necessary regarding the various manufactured preparations of the thyroid gland, some of which are impure and even dangerous, owing to the careless handling or fraudulent substitution.

The toleration of thyroid-feeding does not depend upon the volume, but upon the functional activity, of the gland, and this fact, together with the evidences of toxic action reported in some instances of the administration of thyroids to a maximum degree, make it important to urge again—as intimated above—the necessity of small dosage at the

¹ *Lancet*, Sept. 30, 1899.

² Osler, in the *Amer. Text-Book of Therapeutics*, pp. 926, 927.

beginning of treatment, and the most careful and judicious increase in the quantity given. The additional fact of an occasional cumulative action should also be emphasized. Should vomiting, renal pain, tachycardia, suffusion of the face, syncope, vertigo, or marked headache supervene, the remedy should be stopped at once. The treatment may be resumed again cautiously, alternating with intervals of cessation. I have observed that by combining arsenic with any of the preparations of thyroid the toxic effects of the latter can be in great measure obviated. Good results are obtained usually within a month, though it is probable that even after all the symptoms have subsided the treatment may have to be continued at intervals. The activity of the thyroid is enhanced by the presence of iodine (Hunt and Seidell).

Cretinism, Sporadic and Endemic.—Here there is a congenital atrophy or absence of the thyroid gland, or an enlargement by the growth of fibrous tissue at the expense of the glandular elements. Cretinism may also develop in early infancy. The patients are often the children of parents having various neuroses and goiter, and syphilis has also been supposed to have a causative influence. Congenital myxedema is quite common only in regions where goiter is endemic. A marked sporadic case has been in the Philadelphia Hospital for many years.

Symptoms.—Cretins are dwarfs with large heads and faces, thick lips, thick protruding tongues, broad bodies and members, and prominent abdomens. The subcutaneous tissues are myxedematous. Umbilical hernia is often present. The mental condition is that of idiocy, and physical growth is retarded and slow. Speech is unintelligible or nearly so, and the voice harsh. Walking may never be accomplished, and is always slowly developed. There is anemia, the blood being of a fetal type. Rheumatic symptoms sometimes occur.

Prognosis.—The disease is progressive until about the fifteenth year in those cases developing during early childhood. Congenital cases usually die shortly after birth. At the twentieth or thirtieth year "the mental and physical characters are those of childhood."

Treatment.—Thyroid-feeding has been followed by beneficial results, the checked growth having recommenced and the cretinic aspect having been largely lost. S. Küh¹ has employed iodothyron in one case with quite as satisfactory results as those from the dried thyroid. Pahr² has implanted a portion of the thyroid gland of the mother into the spleen with manifest amelioration of the mental state of the child.

Operative Myxedema, or Cachexia Strumipriva.—Extirpation of the thyroid for surgical reasons has given rise to the gradual production of symptoms and conditions identical either with true myxedema or with the cretinoid state. Partial removal of the gland is not followed by cachexia strumipriva, nor is complete thyroidectomy when accessory glands are present elsewhere.

The administration of raw or broiled thyroids, or of their various extracts or preparations, must also be employed in this form of myxedema, and should be continued throughout the rest of the patient's life, perhaps with intervals of withdrawal of the feeding until the improvement gained begins to lapse.

PART V.

DISEASES OF THE RESPIRATORY SYSTEM.

I. DISEASES OF THE NOSE.

ACUTE RHINITIS.

(*Acute Nasal Catarrh; Acute Coryza.*)

Definition.—An acute catarrh of the Schneiderian membrane, sometimes tending to involve the adjacent sinuses and passages. It is known to the laity as “cold in the head.”

Etiology.—Its most conspicuous cause is exposure to draughts of air and to the influence of the atmospheric vicissitudes that are especially prevalent during the winter and spring seasons. It often results from the inhalation of irritants (physical, chemical, or biological). It may also display epidemic behavior, and this fact points strongly to its microbic origin. Hence local disturbances of the circulation due to exposure are to be regarded as the accidental means of preparing the soil for bacterial invasion. Acute rhinitis may be also secondary to, or propagated from, inflammations of the faucial mucosa by contiguity.

Symptoms.—Sensations of *chilliness*, succeeded by *feverishness* (the temperature reaching 100° to 101° F.; 37.7°–38.3° C.), frequent *sneezing*, *headache*, and a feeling of general ill-health are among the prominent features that attend the development of coryza. Pains in the extremities and back tend to appear only in severe cases. The pulse is frequent, the skin dry and unduly warm, thirst is increased, while the appetite is impaired, and constipation often attends. The *nasal mucosa* is swollen, and thus interferes both with the nasal respiration and the senses of smell and taste; its color is deepened, its surface covered at first with opaque mucus, and later with a muco-purulent secretion. Among early symptoms is the discharge of a watery, irritating secretion from the nares and a maceration of the epidermis, with resulting abrasions. On account of the swelling of the mucosa of the lacrymal ducts the tears flow down over the cheeks. Adjacent mucous surfaces may become involved, giving rise to conjunctivitis, catarrhal pharyngitis, laryngitis, and finally, in the severer types, bronchitis. Naso-labial herpes is not uncommon. As the affection progresses the secretion becomes more abundant and turbid and more or less pyoid. The symptoms due to extension of the catarrhal inflammation vary with the organs or structures involved. The disease runs its *course* within five or six days, but

the nasal discharge, which gradually diminishes, usually persists for a few days longer.

Diagnosis.—In the presence of the above-mentioned symptoms the disease is readily recognized. In well-marked cases, however, the possibility that an infectious disease may be developing, the beginning of which is characterized by nasal catarrh (measles, influenza, etc.), is to be recollected.

Prognosis.—Except in neglected cases, which result in bronchitis, and occur at one or other extreme of life, the disease is free from danger. The nursing infant may have to be fed with a spoon temporarily.

Treatment.—At the outset a purge, consisting of calomel (gr. ij—0.129), or a pill of blue mass (gr. v—0.324) at night, followed by a Seidlitz powder in the morning, is advisable. To children a dose of castor oil may be given. The early administration of a diaphoretic, such as Dover's powder (gr. v—x—0.324—0.648) at night may arrest the complaint, and quinin in a large dose (gr. xij—xv—0.777—0.972) at night may cut short the course of the disease. When the above-mentioned abortive measures fail, the following tablet produces good results:

| | |
|-----------------------|-------------------|
| R. Quinin. sulphat., | gr. ijss (0.162); |
| Fluidext. belladonnæ, | ℥jss (0.099); |
| Sodii salicylatis, | gr. xxx (1.944); |
| Camphoræ, | gr. ijss (0.162). |

M. et ft. tablet No. x.

Sig. One tablet every hour or two.

For the fever aconite may be employed, and, if the throat be involved, bryonia may be given in conjunction.

Local Treatment.—This aims at soothing as well as at reducing the swelling of the Schneiderian membrane. The compound tincture of benzoin forms a soothing inhalation (ʒij to a pint—8.0 per half liter—of water) when raised nearly to the boiling-point; the vapor is inhaled for ten or fifteen minutes at a time. With a view to reducing the swelling a solution of cocain (strength 2 to 4 per cent.) may be temporarily used; Mackenzie recommends this admirable combination:

| | |
|------------|----------------|
| Menthol, | gr. v (0.324); |
| Pinol | ℥v (0.324); |
| Benzoinol, | fʒj (32.0). |

In severe cases the patient should be kept in-doors and in an atmosphere of even temperature.

CHRONIC RHINITIS.

(*Chronic Nasal Catarrh.*)

Two forms are recognized, the hypertrophic and atrophic, and these, though, as a rule, occurring separately, may be found in combination.

Pathology.—The morbid changes in hypertrophic rhinitis consist in an enlargement of the lower turbinated processes, together with redness and swelling of the nasal mucosa that may be general or limited

either to the anterior or posterior nares. As the disease progresses the thickening of the membrane increases, until it finally encroaches upon the nasal chambers at every point. In addition to the nasal obstruction there is a hypersecretion of mucus. Opposite changes occur in atrophic rhinitis, such as thinning or atrophy of all the structures, with enlargement of the nasal cavities. The nasal mucosa is coated with thick, yellowish-green, decomposing crusts, which emit a characteristically fetid odor, and the frontal, ethmoid, or other accessory sinuses may, by an extension of the inflammation from the nasal chambers, be invaded by mucopurulent inflammation. The atrophic process does not affect the glandular structures of the upper third of the nose, and this fact explains the most unpleasant feature of the affection—namely, the horrible secretion.

Etiology.—Frequently occurring attacks of acute rhinitis may produce the chronic form, and syphilis and, less commonly, tuberculosis are also among its causes. Abel¹ regards atrophic rhinitis as infectious, claiming that the cause is the *bacillus mucosis ozenæ*, which resembles closely the pneumobacillus, but is distinguishable from it.

Symptoms.—(a) In the *hypertrophic* form nasal respiration is impeded, owing to the hypertrophy of the turbinated bodies. The sense of smell is impaired, and there is a discharge of secretion from the nares, particularly the posterior, inducing “hawking.” The diagnosis is set at rest by a rhinoscopic inspection of the parts. While this is a common affection everywhere, it is wellnigh universal in this country.

(b) In chronic *atrophic* catarrh there is some degree of nasal obstruction, occasioned by the presence of the thick crust, but the most conspicuous symptom is the disgusting odor, which makes the patient repellent in society. The sense of smell is lacking. After cleansing the membrane the rhinoscope will show the nasal chambers to be unduly capacious.

Treatment.—(1) **Chronic Hypertrophic Rhinitis.**—The treatment is divisible into *general* and *local*. The physician should procure an environment for his charge most favorable for promoting the general nutrition, which is often below the health-standard. The selection of a suitable climate, then, forms an important part of the management, and a residence in a locality that possesses a mild, equable, comparatively dry and pure atmosphere is to be advised and encouraged. Various tonics may then be demanded by the general condition of the patient, and strychnin and electricity are useful in restoring the loss of power in the contractile elements of the intercellular walls.

Local measures are employed to facilitate thorough cleanliness and

FIG. 42.—Apparatus for cleansing the nasal passages in chronic rhinitis.

¹ *Zeit. f. Hyg. u. Infektionskrankh.*, Bd. xxi. H. 1.

disinfection of the affected parts, though in incipient and mild cases energetic treatment is scarcely needful. The best method of cleansing the nasal passages is by means of the coarse spray (Fig. 42). The apparatus of Lefferts is also to be employed when the secretion is inspissated or tightly adherent. An excellent combination for use in this manner is the following:

| | | | |
|----|------------------|-------------------|------------------------------|
| R. | Sodii bborat., | | |
| | Sodii bicarb., | \mathfrak{aa} . | \mathfrak{zj} (4.0); |
| | Phenolis, | | gr. viij (0.518); |
| | Listerin., | | \mathfrak{zj} (32.0); |
| | Aquæ destillat., | q. s. ad | \mathfrak{ziv} (128.0).—M. |

Sig. Use as a spray three times daily.

It is often desirable to use warm or even hot liquids, in which case the application is made by the use of the anterior and posterior nasal syringe. Powders are harmful, and, as the nasal douche is dangerous in unskilled hands, these should both be abandoned.

In hypertrophic rhinitis the obstruction to nasal breathing is to be removed, and to accomplish this caustics (chromic, glacial acetic, and nitric acids) are used, of which the most efficacious is chromic acid. This should be applied by means of a pointed glass rod, the application being followed by a sloughing away of the diseased tissues. Among other modes of removing the nasal obstruction that may be mentioned are the galvano-cautery, the thermo-cautery, and the cold-wire snare; these modes, however, are practised chiefly by the specialist.

(2) In **atrophic rhinitis** a cure is to be despaired of, but the patient can be rendered free from the offensive discharge, and hence to a great degree comfortable. As this is often but an advanced stage of hypertrophic nasal catarrh, the general treatment is similarly directed: it is therefore well to overcome, as far as possible, by a mental stimulus, the depressed mental state due to the fetor. If the diathesis be tuberculous, cod-liver oil, iron, arsenic, and strychnin, together with a generous diet, are to be advised. If syphilis is associated, appropriate measures must be instituted. Moreover, since a subject of atrophic rhinitis is a fertile source of atmospheric contamination, his living and sleeping apartments must be highly ventilated.

Local Measures.—An antiseptic spray of Seiler's or Dobell's solution, and oiling the nasal cavities, are measures to be first tried. If they prove non-efficacious, the crusts may then be removed with a cotton applicator coated with a solution of hydrogen peroxid. We may then use a spray of liquid albolene and menthol; this serves not only to lubricate, but to supply moisture, both of which are important therapeutic indications. Small ulcerations occur in this affection and induce oft-repeated epistaxis; consequently, an attempt should be made to heal the latter and to obtain an even, moist surface. To accomplish this the method of Clarence C. Rice may be followed—*i. e.* to rub the ulcerations thoroughly by means of a cotton-carrier with a small hard pledget of cotton moistened with listerin or borolyptol for a few seconds at a time. These antiseptic frictions are made at intervals of two or three days for two or three weeks.

AUTUMNAL CATARRH.

(Hay Asthma; Hay Fever.)

By this term is meant a form of asthma that occurs exclusively during the warm season (spring and late summer, particularly).

Etiology.—The direct causes are the odorous principles given off from certain plants (the pollen of the *Anthoxanthum odoratum*, of the rose, etc.), and inorganic dusts of various sorts. In some instances it appears to arise without obvious exposure to a special irritant—for example, it may be excited by strong emotional disturbance. Kyle¹ has advanced the theory, based on experimental studies, that the disease is caused by chemic changes of the mouth secretions.

Predisposing Factors.—The male sex suffers more frequently than the female. Age has a slight though decisive influence, more than 33 per cent. of the cases occurring before the twentieth year. Often some abnormality of the nasal passages (e. g. a polypoid tumor, hypertrophy of the mucosa, a deflected septum) acts as a source of reflex irritation. Heredity is among the potent contributing causes. The inhabitants of cities are more liable than those in rural districts, though the air of agricultural regions intensifies the condition. Perfect immunity is enjoyed by the dwellers in certain climates—chiefly mountainous and marine. Perfect health probably confers immunity.

Symptoms.—The symptoms are (a) local and (b) general.

(a) **Local.**—Hay fever has an abrupt onset, and the attacks return annually at or about the same time. The invasion is marked by pronounced coryzal symptoms, with much sneezing, stoppage of the nasal passages, copious rhinorrhea, the discharge being thin and watery as a rule, and rarely mucopurulent. Suffusion of the eyes, with itching of the lids and free lacrymation are constant features; the decided itching sensation of the palate and pharynx is also at times a very distressing symptom. The sense of smell may be lost, and taste and hearing are often impaired.

The course as regards the local symptoms is marked by alternate amelioration and aggravation of the symptoms, the exacerbations being due to exposure to the open air, especially in changeable weather. Later the catarrhal process invades the bronchi, and cough and asthmatic seizures appear, these often becoming very distressing.

(b) **General disturbances** comprise subjective sensations—anorexia, insomnia, lassitude, and chilliness alternating with slight feverishness.

The course is from four to six weeks, and cases that develop in August are terminated by the occurrence of a decided frost. Wyman also describes the "rose cold," which comes on in the spring.

Diagnosis.—The recognition of hay asthma is unattended with difficulty, provided that such facts as the time of its occurrence (June) and its annual periodicity are carefully noted. The sudden onset of severe coryza-like symptoms in a neurotic person, particularly in the month of August, should direct attention to autumnal catarrh.

Prognosis.—This is favorable both as to life and length of days, though a permanent cure is a rare event unless permanent removal from the influence of the specific causes can be effected.

Treatment.—Whenever possible the patient should travel till he

¹ Jour. Amer. Med. Assoc., October 1, 1904.

finds a locality in which he ceases to suffer, and subsequently he should there spend the period of annual attack, and by these means escape the exciting causes. The Adirondacks and White Mountains usually bestow immunity. If the patient cannot make the necessary change, the general nutrition is to be improved by hygienic means and the use of such measures as phosphorus, strychnin, quinin, and arsenic.

The local symptoms demand the topical application of various agents to the nasal chambers, such as cocain hydrochlorate solution (1 per cent.); if applied on cotton with a probe, followed by a 4 per cent. solution of antipyrin, the palliative effect is prolonged (Gleason). Hollopeter has had good success by daily *sterilizing* the nasal chambers by means of Dobell's solution used first with an atomizer; then swabbed thoroughly over the naso-pharynx. The membrane is then dried and the nose loosely plugged with cotton saturated with a mild solution of menthol in albolene. Of 1240 patients who used serum-therapy (Pollantin) correctly, 56.1 per cent. either remained free from attacks, or could abort attacks already started (Dunbar). Atropin allays the irritability of the mucous membrane involved and diminishes the rhinorrhea, thus mitigating the constitutional disturbances and sometimes relieving the asthmatic paroxysms. When given internally the dose should not exceed gr. $\frac{1}{300}$ (0.0002), to be repeated every hour till dryness of the throat appears.

My own best results have been derived from the hypodermic use of this drug (gr. $\frac{1}{200}$ —0.0003) at intervals of three to four hours till the desired effect is produced. Gleason has obtained satisfactory results from nitro-muriatic acid freshly prepared (dose \mathcal{M} v t. i. d. after meals in a tumbler half full of water). Recently the internal use of 5 grain tabloids of suprarenal extract has met with fair success in the hands of S. Solis-Cohen and others. Adrenalin chlorid applied locally has given good results in many cases.

EPISTAXIS.

(Nose-bleed.)

Etiology.—The causes of nose-bleed are various, and a convenient grouping is the following: (*a*) Affections of the nasal mucosa (*e. g.* ulcer, polyp, intense hyperemia). (*b*) Injuries, either external, as from a blow, or internal, as from plugging with a foreign body, nose-picking, etc. In this category may also be included epistaxis due to fracture at the base of the skull. (*c*) Acute infectious fevers, particularly typhoid (at the onset) and influenza. (*d*) Chronic affections, such as pernicious anemia, leukemia, and hemophilia. (*e*) Vicarious menstruation. (*f*) Rarefaction of the air. (*g*) Plethora; here may be mentioned cerebro-congestion with intense headache. (*h*) Severe over-exertion. (*i*) Frequent epistaxis may be caused by arterio-sclerosis even in the earlier stage while yet amenable to treatment. (*j*) Chronic interstitial nephritis; mitral disease.

Symptoms.—Except when due to traumatism the blood usually drops slowly from one and occasionally from both nostrils. Rarely, the blood may flow as a continuous stream or the nares may present a projecting coagulum. The blood may also gravitate into the pharynx and

be coughed up, or it may be swallowed and vomited. A rhinoscopic examination often reveals the source in cases in which a previous diagnosis of hemoptysis or hematemesis has been made.

The immediate results of nose-bleed are weakness and a moderate anemia, but these are not prolonged, as a rule. Cases arising from fracture at the base of the skull will generally prove fatal.

Treatment.—A careful search for a local cause is especially demanded in cases in which there are frequently recurring attacks. In most cases a spontaneous arrest occurs, but if not, a resort to simple household measures, such as the application of ice to the nose or to the back of the neck, holding the hands up, or the injection of very cold or very hot water into the nares, are to be encouraged. Various astringents (tannic acid, acetate of lead, alum, zinc) may be employed, and a saturated solution of antipyrin is also highly praised. Adrenalin chlorid is valuable. When an ulcerated bleeding point can be reached, there may be applied to it a solution of chromic acid or it may be cauterized by solid silver nitrate. Prolonged pressure applied upon the facial artery as it passes over the inferior maxilla may be efficacious. A solution of gelatin may be injected into the nostril. I have little confidence in internal astringent remedies. The oil of erigeron, administered in large doses, has seemed to do good in a few of my own cases, but in obstinate cases the posterior nares should be plugged, preferably with gauze lubricated with oil or petrolatum, to avoid recurrence when packing is removed. Tincture of aconite or nitroglycerin may be used in arterio-sclerotic conditions.

II. DISEASES OF THE LARYNX.

ACUTE CATARRHAL LARYNGITIS.

(*Acute Endolaryngitis.*)

Definition.—An acute catarrhal inflammation of the larynx, characterized by cough, hoarseness, and painful deglutition.

Pathology.—The anatomic changes present during life are all lacking *post mortem*.

Etiology.—Acute laryngitis may be a primary affection—and particularly *laryngitis sicca* (Molinie)—but oftener it is associated with and secondary to catarrh of the nose and nasopharynx. Wright attributes *laryngitis sicca* to the coccus of Löwenburg.

Catarrhal laryngitis has for its chief direct causes traumatism, exposure to cold and dampness, the inhalation of irritating vapors or gases, rheumatism (rarely), and the corrosive effect of certain poisons and hot fluids. A certain degree of predisposition is engendered by immoderate smoking, particularly by the cigaret-habit, and by the use of concentrated alcoholic drinks. These agencies induce hyperemia of the laryngeal mucosa, which is easily converted into active inflammation. Acute laryngitis is often associated with acute infectious diseases.

Symptoms.—There are two conspicuous symptoms—*alteration in the voice* (hoarseness) and *cough*. At first there is merely a huskiness

of the voice, but later there may be pronounced hoarseness or even complete aphonia. The cough is dry and characteristically painful until secretion is free. In the early stages the patient complains of sensations of tickling or the presence of some small object in the larynx, causing a frequent desire to clear the throat. In severe instances deglutition is painful. Edema of the larynx may tend to supervene and cause intense dyspnea, with a feeling of distressing oppression. There is, as a rule, a slightly elevated temperature.

FIG. 43.—Method of making a laryngoscopic examination.

The patient is placed in front of the operator, on an arm-chair, with the back of the chair high enough to afford his head a comfortable rest, and with the source of the light over the right shoulder. The operator then adjusts the head-mirror (the fixed apparatus), warms the throat-mirror over a light sufficiently to prevent the moisture of the breath from being deposited upon it, and touches the hand with the mirror before passing it into the mouth, so as not to use it too hot. The patient's tongue is then protruded, and by means of a napkin is seized between the thumb and the fore-finger and drawn well forward to lay the fauces open to observation. The throat-mirror is then held in the right hand in the same way as one holds a pen. "Finally, it is introduced into the mouth, its handle being inclined downward and outward, its base being parallel with the dorsum of the tongue; it is then passed backward without altering this relation until the edge of the mirror nearly touches the soft palate, the shaft of the mirror in this movement striking the angle of the mouth as a resting-place and fulcrum. The subsequent movement consists in turning the mirror by twisting its shaft between the fingers until it is inclined at an angle of 45 degrees to the line of vision; then it is carried backward and downward until the uvula rests upon its posterior surface, when it is lifted boldly upward and backward until its lower edge comes entirely into view again and rests firmly against the posterior wall of the pharynx. The patient should then be directed to sound in a somewhat high key 'a,' which lifts the larynx and at the same time the epiglottis, and exposes and brings into view the laryngeal cavity" (Bosworth).

It is important that the mirror itself should be kept in the median line, with its plane always at right angles with the field of vision, as shown in the illustration. In making a laryngoscopic examination we note any abnormalities of color-appearance (the natural being a rose-pinkish tint), of the outline of the different parts, and the deviations from the symmetrical movements of cords, if any, etc.

The laryngeal mirror brings to view a characteristic picture—a swollen, tumefied, and reddened mucosa. These changes affect the vocal cords (whose pearly-white appearance is now lacking) and the ary-epiglottidean folds. It is usual to note also redness and swelling of the epiglottis above and of the trachea below. After secretion has occurred a mucoid covering in streaks or patches is noticeable.

Diagnosis.—This is easy in the presence of marked hoarseness, dry cough, and the image afforded by the laryngeal mirror (Fig. 43). In very early life the larynx cannot be successfully examined; still, *laryngismus stridulus* (owing to the absence of fever, coryza, etc.) could hardly be mistaken, as has been supposed, for acute catarrhal laryngitis. The same is true of *membranous laryngitis*, if we bear in mind the characteristic local features and the more intense constitutional disturbances of the affection.

Treatment.—The physician must enjoin against the use of the voice. The very young and the aged should, in severe or even moderate cases, be kept in bed, and should occupy a single apartment in which the atmosphere is uniformly moist and warm, the temperature ranging from 75° to 80° F. (23.8°–26.6° C.). Inhalations of moist air or steam are of great service, and I have long been in the habit of recommending the following simple apparatus and method of carrying out this mode of treatment: An ordinary tin cup, small pitcher, or other vessel is filled with boiling water to which 1 or 2 drams (4.0–8.0) of the compound tincture of benzoin have been added; the steam is then collected by inverting over the vessel an ordinary funnel. The patient is allowed to inhale the steam by placing the mouth over the narrow neck of the funnel above, or a piece of rubber tubing may be attached to the end of the funnel that is uppermost.

Steam atomizers admirably meet the necessities of the case; and in the case of children the vapor of benzoin, eucalyptol, and other equally sedative and stimulating substances may be diffused in the air of the sick-room. Concentrated solutions or insufflations of powders are not without harmful influence, and neither the cotton-carrier nor the mop should be allowed to enter the larynx in this affection. The external application of the ice-bag or cold compress tends to mitigate the inflammatory process and to obviate spasm.

The *general* treatment differs with the special stages of the complaint. If the case is seen early, a full dose of quinin (gr. xij–xvj—0.777–1.036) may serve to successfully abort the attack, and, in conjunction Dover's powder (gr. v–x—0.324–0.648) may be prescribed. Codein sulphate may be given at prolonged intervals during the attack, and frequently at night, to allay cough; this remedy may be combined with ipecac, aconite, and liquor ammonii acetatis to facilitate secretion and render the cough humid. If we except the abortive measures, the constitutional is wholly inferior to the topical treatment of this variety, though the existence of any particular diathesis may require special internal remedies.

CHRONIC LARYNGITIS.

(*Chronic Endolaryngitis.*)

Pathology.—The laryngeal mucosa is thickened and somewhat reddened, and erosions amounting to superficial ulcerations are rarely seen. A prominence of the mucous glands, especially of the ventricles and epiglottis, is noticeable. Fine villous projections from, and nod-

ular swellings in, the vocal cords are among the rarer morbid changes. Minute vesicles may arise upon the surface (*herpetic laryngitis*).

Etiology.—Of repeated acute attacks frequently cause chronic laryngitis, and the long-continued use of the voice (as in public speaking or singing), the inhalation of an atmosphere laden with mildly irritating impurities (tobacco smoke, etc.), and an immoderate indulgence in alcoholic stimulants, respectively or unitedly, predispose to, if they do not excite, the disorder.

Symptoms.—As in the acute form, *hoarseness* and *cough* are the two especially prominent symptoms. The former may be so slight as to present merely a rough tone, or it may involve an almost total loss of voice. The cough shows similar variations in severity, sometimes consisting of a short hack, and again occurring in spasmodic and ringing paroxysms, due to a sense of tickling in the larynx. There may be a small amount of mucous or muco-purulent expectoration, but for prolonged periods the cough may be dry and ineffectual. *Local pain* and discomfort sometimes supervene, and are excited generally by attempts at speaking or singing—events that aggravate all the other symptoms. To complete the diagnosis, the laryngeal mirror is required to show a swollen and slightly red membrane, with a distention of the mucous glands in the immediate vicinity of the epiglottis and ventricles, and occasionally superficial erosions.

Prognosis.—This is unpromising as to complete recovery, although it presents no grave dangers. It is incurable in those instances in which the causal influences cannot be removed, and in all cases in which the patient fails to lend hearty co-operation.

Treatment.—This is (*a*) *hygienic* and (*b*) *medicinal*. (*a*) The sanitary measures embrace preventives that are directed to the removal of all the etiologic factors, whether merely predisposing or exciting. The voice demands rest and the prohibition of smoking and the use of alcoholics in excess, and the patient must also avoid the close, contaminated air of the crowded hall, theatre, and like places. In addition, a tonic regimen, with a view to energizing the nutritive processes, is to be encouraged. In many instances the environment is best arranged with reference to the commonly associated conditions—especially the morbid processes in the nasal and naso-pharyngeal cavities. “A sea-voyage or residence at the sea-shore is, in the large majority of instances, productive of good, and the effects of surf-bathing are often magic” (Mackenzie). My own practice has been to send subjects of chronic laryngitis to pine-forest resorts at low elevations that afford a pure, equable, and somewhat stimulating atmosphere, and I have found that in many cases the selection of a proper climate constitutes the most important part of the treatment. (*b*) The *medicinal* treatment is both local and general. The latter should include creasote, cod-liver oil, and other tonics. Expectorants are of little if any value. The *local* measures, however, are important. Moderate exposure of the neck and daily ablution with cold water are to be advised, and attention to the nose and naso-pharyngeal cavity is of prime importance.¹

A long list of applications to the larynx from within, including local astringents, disinfectants, and alcoholics, might be enumerated. Of

¹ J. C. Wilson's *American Text-book of Applied Therapeutics*, p. 791.

astringent solutions, however, the best are tannic acid (1–2 per cent.) or alum (.5–1 per cent.) and zinc sulphate (3–5 per cent.). These may be sprayed into the larynx by means of a compressed-air machine with spraying-tubes, although all of the different kinds of inhaling apparatus more commonly used will answer the purpose. If the ordinary hand-atomizer be used, the patient should be taught to draw the vapor into the larynx by gentle and frequent acts of respiration. Disinfectants, such as creasote, potassium chlorate (the latter if ulcerations be present) in solutions of suitable strength, may be used in like manner. I can confidently advise as useful alteratives both iodine and silver nitrate, commencing with a weak solution of the latter (gr. v–3j—0.324–4.0), and the strength being gradually increased until the maximum strength that can be endured without distress is reached (gr. xx–3ij—1.296–8.0). These topical applications should be made directly with a cotton-carrier or brush at intervals of three or four days, preceded by the use of a cleansing spray. The many astringent and sedative lozenges found in the market are only slightly palliative in their effects, and their prolonged use tends to excite gastric disturbance. I am unalterably opposed to the insufflation of powders, believing that they are capable of augmenting the laryngeal irritation and of adding fresh irritation in adjacent parts, particularly in the tracheo-bronchial tract.

SPASMODIC LARYNGITIS.

(*Laryngismus Stridulus*; *False Croup*.)

Definition.—An affection peculiar to children, chiefly of nervous origin, though also, according to Strümpell and others, often associated with acute catarrhal laryngitis.

Etiology.—The affection is almost solely limited to children between six months and five or more years of age. It is sometimes excited by strong passion or emotion, and it may be associated with tetany. Rachitic subjects are peculiarly liable. The causes of spasmodic croup are in great part those of acute laryngitis.

The mode of action of the direct causes is unknown, but the spasm of the adductors that causes the urgent dyspnea is probably reflex and due to peripheral irritation.

Symptoms.—Two clinical varieties are to be distinguished: (1) That in which the larynx is free from catarrhal inflammation, or the *purely nervous type*. This is especially characterized by sudden brief attacks of dyspnea, either by day or night (often on awakening), that terminate in a high-pitched crowing inspiration ("child-crowing"). The face during the spasm is cyanotic. General convulsions have been noted, but there is neither cough, fever, nor hoarseness. The attacks may be frequently repeated within a single day.

(2) Spasm of the larynx, *associated with mild catarrhal laryngitis*. The attacks generally begin suddenly, about midnight or toward morning on awakening from a sound sleep. Positive evidence of the affection is afforded by the croupy, ringing cough, combined with the hard, stridulous breathing. An approaching spasm may be announced by a harsh

cough and slightly stridulous breathing in the sleeping child. During the attack the countenance may be cyanotic and the breathing most distressing, but these and the above-mentioned severer symptoms generally cease abruptly in an hour or two, and the child resumes its slumber. In my experience the attacks have been repeated for two or three nights in succession, and rarely oftener except in the severest cases. Not infrequently the child manifests the symptoms of mild catarrhal laryngitis between the attacks. A brassy, croupy cough may also attend.

Diagnosis.—*Membranous laryngitis* may be mistaken for spasmodic croup. The development of the dyspnea, however, is more gradual, is without intermission, and without relation to the period of the day. Albuminuria and a false membrane in the throat or nares are usually present in *laryngeal diphtheria*.

Prognosis.—Although the appearance of a paroxysm is alarming, the disease is practically free from danger.

Treatment.—1. The treatment of laryngismus stridulus is quite similar to that of infantile convulsions. A warm bath at a temperature

Fig. 44.—Croup-kettle in use.

Four upright rods (5.7 inches in length) are fastened to the legs of the bedstead by a wire or string. Two side-rods are tied on the uprights, and two end-rods (length dependent on width of bed) rest upon the side-rods. These rods form a complete framework for the sheets to hang upon. Four sheets are required (11-4 size)—three to cover the ends and sides, and one to be placed on top. One side should be completely closed, while the opposite is to be left open for ventilation or to be adjusted according to circumstances.

of 98° to 105° F. (36.4°–40.5° C.) is the best means of breaking up the spasm. While in the bath cold sponging of the back and chest is serviceable. The finger may be passed into the fauces, and should the epiglottis “become wedged in the chink of the glottis, it must be released by the finger.” After the attack active treatment should be directed at the discoverable causes, and I have been in the habit of giving

small doses of the bromids thrice daily, together with warm cod-liver oil inunctions, with striking effect.

2. In spasmodic croup an emetic is to be given at once, the best being a mixture of alum and syrup of ipecac, of which the dose is 3j (4.0), to be followed by irritation of the fauces with the finger in order to facilitate emesis. In severe paroxysms a hot bath may be given to aid the emetic. In case the dyspnea is not checked by the above measures, chloral hydrate may be exhibited by enema (gr. ij-v; 0.129-0.324) or a whiff of chloroform may be given. The local application of cold (ice-collar, ice-water cloths) is useful, and sinapisms placed around the throat and over the chest also tend to arrest the spasm. The use of steam-inhalations from the so-called croup-kettle (Fig. 44) is of signal service, and should be more widely employed, particularly when it is inconvenient to use the hot bath.

Between the paroxysms the patient should receive a mild laxative, such as calomel or castor oil, and, in addition, the treatment appropriate in acute catarrhal laryngitis. To prevent recurrences an environment calculated to increase the nervous tone of the child is to be procured, and it is especially advisable to accustom him to the outer air, though protected by suitable dress and without undue exposure to draughts.

EDEMATOUS LARYNGITIS.

Definition.—An infiltration of the mucous membrane of the larynx with serum. In most cases it is a true inflammatory edema.

Etiology.—Two chief classes of causes are operative: (1) Those that excite inflammation. The condition may complicate acute laryngitis, though oftener it appears in chronic affections of the larynx, and particularly if ulceration be associated (*e. g.* tuberculosis, syphilis); it may also appear in connection with certain infectious diseases (erysipelas, diphtheria, typhoid fever). The inflammation inducing the edema may extend from adjacent parts, as the neck, pharynx, and other organs. (2) Factors that tend to excite dropsical effusion. These may be general, as Bright's disease, heart-affections, etc.; or they may be local. Among the latter are enlargements of the cervical and mediastinal lymphatics, aneurysm of the arch of the aorta, thyroid tumors, etc.—*i. e.* conditions that exercise pressure upon the jugular veins. Rice, who studied 41 cases, thinks it doubtful whether edema of the larynx ever occurs from simple catarrhal inflammation.

Symptoms.—In acute cases the initial disturbance is both sudden and severe. There is *dyspnea* that tends to increase rapidly, accompanied by a husky, suppressed voice, with augmenting obstruction. The *respirations* may become stridulous, but there is no cough. The laryngoscope reveals marked swelling of the epiglottis and of the ary-epiglottic folds. Rarely the swelling occurs in or even wholly below the vocal cords. The inserted finger may detect the swollen epiglottis, which may also be seen if the tongue-depressor be used.

Diagnosis.—This can be made with ease from the rapidly developing dyspnea soon reaching the climax, the absence of cough and hoarseness, and by the use of the laryngoscope. In cases in which the epiglottis can be felt or seen a laryngoscopic examination is superfluous.

The **prognosis** is decidedly unfavorable except in the event of early operative interference.

Treatment.—If of inflammatory origin, the ice-bag should be applied to the larynx, and ice should be allowed to constantly dissolve in the patient's mouth. Local depletion, preferably by leeching the front of the neck, is also to be tried, and Levy and Laurens¹ record a case in which a cure followed this measure. If intense dyspnea tends to persist, scarification of the edematous parts with a curved bistoury, the point of which is covered with adhesive plaster, must be promptly instituted, and, if asphyxia threatens, tracheotomy must immediately be performed. Dropsical edema demands scarification, and, if relief does not follow, intubation or tracheotomy.

TUMORS OF THE LARYNX.

THESE may be either benign (fibroma, myxoma, lipoma, chondroma, adenoma, angioma, cyst) or malignant (sarcoma, carcinoma). Of these, papillomata or papillomatous fibromata occur most frequently, especially in infancy. Navratil² records 42 cases of multiple laryngeal papillomata in children whose larynges were extensively filled. These growths may also occur in chronic laryngitis, and, like other tumors of the larynx, they commonly spring from the vocal cords. Their shape, size, and tendency to pedunculation do not differ from their characteristics when noted elsewhere in the body.

Symptoms.—Small tumors may occupy the larynx without producing symptoms. The first feature then noted is *hoarseness*, which gradually grows worse and may end in complete aphonia. If situated in the upper larynx, *cough* is common, and when the tumor causes obstruction of the larynx *dyspnea* supervenes and tends to increase in severity. A mobile growth may cause sudden occlusion of the glottis, exciting orthopnea and threatening asphyxiation. To confirm the diagnosis a laryngoscopic examination is required.

The **prognosis** is favorable in the benign, but unfavorable in the malignant forms.

Treatment.—This is altogether surgical, though Delavan states that 3 cases of papilloma have been cured by frequently repeated sprays of absolute alcohol. Curetting is often followed by a recurrence, while laryngo-fissure and thorough removal of the growths restore speech and prevent recurrence.

III. DISEASES OF THE BRONCHI.

CATARRHAL BRONCHITIS.

(*Tracheo-bronchitis*.)

Definition.—A catarrhal inflammation of a part or the whole of the mucous membrane of the bronchial tubes. The mucosa of the

¹ *Arch. gén. de. Méd.*, Dec., 1895.

² *Berl. klin. Woch.*, Mar. 9, 1896.

trachea is also involved to a greater or less extent, and hence the term tracheo-bronchitis is quite appropriate, being descriptive of the seat and character of the disease. Involvement of the bronchioles may also take place, but not without an involvement of the corresponding alveolar structure, the condition being then, with propriety, termed "broncho-pneumonia." Hence the term "capillary bronchitis," still often employed to describe the latter condition, is not pertinent. A certain class of cases is met with, however, in which the catarrhal inflammation, as the result of downward extension, implicates the smaller bronchial tubes without involving the bronchioles; to such the term "capillary bronchitis" might be appropriately given.

The disease may be acute or chronic, both of these forms occurring either as a primary or secondary affection.

ACUTE BRONCHITIS.

Pathology.—The portions of the mucous membrane of the trachea and bronchi that are implicated become reddened and swollen; they are covered with mucus mingled with epithelial cells, and later muco-pus. Some of the smaller bronchial tubes are dilated. The mucous glands are swollen.

The histologic changes may be briefly stated as follows: desquamation of the ciliated epithelium, edema and swelling of the submucosa, and, in the severer grades, infiltration of the latter with leukocytes.

Etiology.—With rare exceptions tracheo-bronchitis is produced by the direct extension of a catarrhal inflammation from the nares, pharynx, and larynx. Rarely the bronchi are the seat of primary acute catarrh, and in the latter instances the upper air-passages may be implicated secondarily, constituting a reversal of the direction of extension.

The immediate causes are mechanical, chemical, and biologic irritants, which act directly upon the tracheo-bronchial mucosa; and that bronchitis is frequently due to infection at a time when the resisting power of the system is reduced there can be little doubt. Among organisms commonly met with is the so-called *micrococcus catarrhalis*. The circumstances disposing to bronchitis are numerous, those pertaining to the individual being—(1) Age, the old and very young being most liable; (2) Debility; (3) Occupation, as in certain trades that expose to irritating vapors and sedentary pursuits. Among the external conditions are—(1) Climatic factors, particularly variability of temperature and humidity; (2) Seasons of the year. "Catching cold" often results from exposure during the spring and autumn months. These two conditions depend substantially upon the same factors. (3) Epidemic influence, which may be independent of influenza.

Acute tracheo-bronchitis arises as a secondary condition in a great variety of diseases, as, for example, the exanthemata and other acute infectious diseases (typhoid fever, measles, whooping-cough, influenza, etc.). As shown elsewhere, among this class of diseases the bronchitis may be dependent upon the primary infectious process; but in many others it is due either to the inhalation of pathogenic irritants or to the retention of bronchial secretions that are apt to accumulate and decompose with resulting bronchitis. The accidental inhalation of particles

of food and saliva may also lead to secondary bronchitis, or the condition may be secondary to chronic affections—*e. g.*, Pott's disease, gout, Bright's disease. Among the toxic causes the poison of uremia must be embraced.

Symptoms.—Bronchitis of the larger tubes, which extends down to about the second division of the bronchi, is spoken of usually as a "cold." In such cases the onset is marked by recurring sensations of *chilliness*, and by *coryza*, slight *sore throat*, and *hoarseness*; while in young and feeble children *convulsions* may occur early. Mild *febrile symptoms* may appear, the temperature ranging from 101° to 103° F. (38.3° to 39.4° C), with slight acceleration of the pulse; and there may be languor and aching in the limbs and lumbar region. With the fully-developed attack substernal soreness, sometimes even *pain*, is experienced, especially on coughing, and the pain may be referred to the intercostal muscles and the line of insertion of the diaphragm. The respirations are increased in frequency, but there is no dyspnea. There may be thoracic oppression and discomfort until the bronchial secretions become free, and there is a *cough* which is at first dry and hard. It often manifests itself in longer or shorter paroxysms, particularly on lying down and on rising after a full night's sleep. At the end of one, two, or more days the cough is moist and attended with an expectoration which is at first *mucoid* and scanty, often viscid, then *mucopurulent* and free; later still it is sometimes distinctly *purulent*. With free expectoration comes relief to the patient. Histologically, the sputum consists mainly of pus-corpuscles with large cells, in which may be seen the so-called myelin droplets of Virchow and carbon particles.

Physical Signs.—Upon laryngoscopic examination the mucous membrane of the larynx and trachea may be seen to be reddened and covered by more or less secretion.

Inspection and *palpation* of the chest are negative, except when the finer tubes become implicated or fever is present, in which case the respirations may be observed to be slightly accelerated. In children the increased rapidity of the respirations is more common and reaches a higher degree. Bronchial fremitus may sometimes be felt. *Percussion* yields negative results, save in very rare instances, in which there occurs a decided accumulation of secretion in the tubes, when there may be found impairment of resonance posteriorly below the scapulæ. *Auscultation* usually renders audible a harsh respiratory murmur, and less frequently piping, sibilant, and sonorous râles. In the advanced stage (with relaxation of the mucosa) large and medium-sized mucous râles are present. The râles change in position from time to time, and after coughing may be altogether absent, only to reappear later.

The **prognosis** varies with the previous constitutional state of the individual. In healthy adults, after a period ranging from a few days to two weeks, the fever subsides, but the cough, though less marked, and the expectoration usually continue for a variable length of time. In old persons and in those of a gouty or tuberculous diathesis the cases pursue a more protracted course. The cases in which streptococci are found in the sputum are severe and in the old may prove fatal. There is in these subjects a tendency on the part of the catarrhal process to extend downward until the finer tubes are implicated, sometimes endangering life. In

the old the secretions are imperfectly expectorated; they gravitate to the most dependent parts and induce bronchiectasis. In young children this downward extension of the affection, with resulting broncho-pneumonia and areas of collapse in consequence of dilatation and occlusion of the bronchioles by muco-pus, is a not uncommon and serious event (e. g. in measles, whooping-cough, *vide Broncho-pneumonia*).

The **diagnosis** is reached without difficulty through the symptoms (slight fever, cough, and expectoration), the acute course, and the physical signs (harsh respiratory murmur, dry followed by moist râles, heard on both sides of the chest). The recognition of the long list of cases that constitute the secondary forms will be made easily possible by noting the circumstances under which they arise.

Differential Diagnosis.—Bronchitis can readily be separated from *pneumonia* and from *pleural effusion* by its history, its lighter course, and especially by the absence of the signs of consolidation and effusion.

When *broncho-pneumonia* develops in the course of bronchitis, dyspnea and fever are increased, cyanosis is present, and the general condition becomes much more grave. There are small patches that yield dulness on percussion, and broncho-vesicular breathing with moist râles can be detected on auscultation.

Bronchitis cannot be separated from the early stage of *whooping-cough*, but when the characteristic cough of the latter is heard all doubt vanishes.

The bronchitis of *measles* before the characteristic eruption appears is distinguished by the red spots ("Koplik's spots") upon the anterior half-arches of the soft palate.

The *acute suffocative catarrh* of Laennec may be confused with the severer forms of bronchitis. Examination of the chest shows nothing beyond coarse rhonchi, the chief distinguishing feature being the acute suffocation. Both *pulmonary tuberculosis* and *influenza* are apt to be confused with bronchitis (*vide* pp. 135, 273).

Treatment.—Not infrequently a "cold" passes through its several stages without rendering the patient ill enough to cause him to seek the advice of a physician, and there are many instances in which but little treatment is required, apart from the usual household measures and protection against cold and damp. If seen early, while the coryza is present, the attack may often be aborted by the use at bedtime of a Dover's powder in combination with quinin (gr. iv–viij—0.259–0.518); this may be seconded by a glass of hot lemonade, with or without a portion of whiskey, and either a hot bath or a mustard foot-bath. The following morning a saline laxative should be taken. To children a mild calomel purge followed by a dose of castor oil may be administered. The patient should be kept in a warm, moist, equable atmosphere—preferably in-doors—and during this period he should take divided doses of quinin for a day or two. If the above mode of treatment fail or if the patient does not come under observation early, the main objects of treatment should be (a) to render the secretions free, and (b) to hasten the expulsion of the sputum after it has been loosened. The first leading indication is to be met by the use of diaphoretics, diuretics, and relaxants. The subjoined formula combines these classes of agents:

R. Potassii citrat., 3vj (23.3);
 Liq. ammonii acetat., 3v (148.0);
 Spt. æth. nit., 3j (30.0);
 Vini ipecac., 3ij (8.0);
 Syr. pruni virg., q. s. ad 3viiij (216.0).—M.
 Sig. 3ss (7.0) in water every two hours until the secretions
 are loosened.

If the temperature in any given case be maintained at a considerable elevation, such as 102°–103° F. (38.8°–39.4° C.) or over, tincture of aconite (Mxvj—1.065) may be added to the above mixture; and if there be present much tickling with distressing cough, due to irritability of the affected mucosa, codein (gr. ij–iiij—0.129–0.194) may be added to the same. For the incessant irritative cough which is present in severe forms of catarrh opium alone is really effective. When the above prescription is not productive of free secretion and troublesome cough continues, I employ the following:

R. Ammon. muriat., 3v (20.0);
 Codeinæ, gr. iv (0.259–0.388);
 Spt. junip. co., 3ss (16.0);
 Mist. glycyrrh. comp., 3iiss (80.0);
 Syr. pruni virg., q. s. ad 3iv (120.0).—M.
 Sig. 3j (4.0) every two hours.

Apomorphin is also excellent as a soothing relaxant in doses of gr. $\frac{1}{20}$ to $\frac{1}{10}$ (0.003 to 0.006) every two hours. Mild counter-irritation by means of mustard-paste, followed by the application of iodine once daily, is also helpful. The patient should keep to his room, in which the atmosphere should be kept moist and of even temperature. (b) The expulsion of the sputum may demand stimulating expectorants, though rarely. It is to be recollected that when the tracheal secretion becomes copious the period of convalescence is usually reached, and stimulating expectorants are then entirely unnecessary. When, on the other hand, the cough is no longer dry, and on auscultation the râles are found to be moist, and whilst, at the same time, the expectoration is expelled with difficulty, or if the bronchitis tends to become chronic, then such stimulating expectorants as senega, squills, and ammonium muriate are to be employed. In cases in which expectoration continues to be too abundant terebene, tar syrup, and oil of sandal are to be resorted to.

Debility and secondary anemia must be speedily overcome by exhibiting quinin, bitter tonics, iron, and arsenic; and a suitable change of air often yields prompt and excellent results in protracted cases. The treatment of the various forms of secondary bronchitis will be considered in their appropriate connections in this work. In the aged the general strength must be maintained; the patient's position must be changed at short intervals and stimulants are usually needed.

Apart from the method above given, of attempting to abort the attack in children, acute bronchitis is in the main to be treated in the same manner as when it occurs in the adult. Opium, however, is to be used very sparingly, and generally in the form of paregoric. If the secretion is abundant and imperfectly raised, it is well to administer an

emetic, such as the wine of ipecac (3ss-j—2.0–4.0), and repeat in ten minutes if necessary. If dyspnea be urgent and cyanosis be marked in the lips and finger-tips, a prompt emetic is imperative in order to save life. A child suffering from acute bronchitis should be kept in bed until the fever subsides.

The diet during the dry stage should consist of liquid forms of nourishment, which should, for the greater part, be taken hot. After the "cold" has been loosened solid food should be resumed.

CHRONIC BRONCHITIS.

Pathology.—The lesions of chronic bronchitis manifest considerable variety both as regards their nature and extent. The epithelial layer is, in great part, missing, and sometimes the mucous membrane is quite thin. In consequence the longitudinal elastic fibers appear unduly prominent. The mucous glands and the muscular coat undergo atrophy in long-standing cases, and the bronchial tubes are dilated (*bronchiectasis*).

In another large group of cases the mucosa is irregularly thickened or infiltrated and granular. Small ulcers corresponding to the mucous follicles are common, and almost constantly emphysema develops in consequence of secondary changes in the vesicular structure.

Etiology.—Chronic bronchitis may either be *primary* or *secondary*. The affection is, however, almost always a secondary one, and, though sometimes the result of repeated attacks of acute bronchitis, it is oftener caused by certain chronic complaints and certain diatheses, as chronic alcoholism, rheumatism, gout, syphilis, pulmonary tuberculosis, and pulmonary emphysema. Organic valvular affections, obesity, and chronic Bright's disease cause *hypostatic bronchitis*. The primary form, which is rare, is the result of exposure to wet or cold or to the daily inhalation of some irritant that produces and maintains a low grade of catarrhal inflammation (dust, vapors). When chronic bronchitis follows the acute form we are often able to detect the operation of some favoring cause, as age, climate, or season. It is most common in the aged, and occurs by preference during the cold season, often recurring regularly in the cold and variable weather of autumn, winter, and spring, and disappearing in summer.

Symptoms.—The symptoms are similar to those of acute bronchitis, though rather less severe. *Pain* is rarely present, the patient complaining merely of a feeling of substernal constriction. There may be soreness at the base of the chest if the cough be frequent and severe, and occasionally in the epigastrium as a result of traction of the diaphragm on the ribs. *Cough*, while not a constant accompaniment, is *paroxysmal* and varies in severity and frequency. The degree of the violence of the paroxysm depends upon two factors—the character of the bronchial secretion and the seat of the catarrhal inflammation. Thus when the expectoration is tenacious and scanty, and when the small-sized tubes are affected, cough is most violent. It also varies both with the weather and the season, as is evident from the fact that there is often an absence of cough in summer, while it returns unfaillingly with each new winter.

The *expectoration* differs widely in different cases. It is sometimes abundant and sero-mucous in character. On the other hand, there are cases of dry cough in which there is little or no expectoration. As a rule, however, it is rather copious, and either *mucopurulent* or distinctly *purulent* in character. *Fever* is usually absent, though rarely a slight rise of temperature occurs at night. The appetite is good as a rule; the bodily weight and nutrition are also well maintained.

Physical Signs.—On *inspection* we usually note undue enlargement of the thorax, with a decrease in expansile movements due to the associated emphysema. Hence *dyspnea* is commonly observed.

Percussion yields a clear or hyperresonant note. Dulness or impaired resonance is sometimes met with, however, during acute exacerbations, especially over the bases, and is due to congestion and edema (Fox). On *auscultation* rhonchi of various forms and moist râles are heard, their number and size being in proportion to the extent of the swelling of the mucous membrane and the amount and fluidity of the secretory products. The respiratory murmur is enfeebled, though roughened, and the expiratory sound is prolonged and wheezy. The right heart may be dilated from increased tension in the pulmonary circuit.

Clinical Varieties.—Special forms, depending largely upon specific causal factors, remain to be described:

1. The commonest variety of chronic bronchitis has been called the "winter cough of the aged," and, as before intimated, is usually accompanied by emphysema and cardiac disease. For this form the gouty diathesis is often responsible. The cough occurs in paroxysms that are most severe at night, and during the early morning hours it is attended with free expectoration of the secretion that has accumulated during the night.

2. *Bronchorrhea*.—In this form there may be an abundant bronchial secretion, composed largely of serum (*bronchorrhœa serosa*). More frequently perhaps the expectoration is purulent and thin, containing greenish or greenish-yellow masses. It may at times be thick and purulent. Dilatation of the tubes and resulting fetid bronchitis may be developed as secondary conditions.

3. *Fetid Bronchitis*.—In this variety the expectoration emits the characteristic odor of decomposing animal substances. The fetor may indicate gangrene of the lungs, abscesses, bronchiectasis, decomposition of matter within phthisical cavities, or empyema with perforation of the lung. Hence these conditions must be carefully excluded before the diagnosis of true fetid bronchitis is made. In the latter disease the expectoration is usually copious, and on standing separates into three layers, of which the uppermost is composed of frothy mucus, the intermediate of a serous liquid, and the lowest of a thick sediment, that presents a granular appearance and is made up chiefly of small yellow masses—the characteristic Dittrich's plugs. Microscopically, the Dittrich's plugs are seen to be composed of microorganisms, chief among which is the *Leptothrix pulmonalis*; they may also contain pus-corpuscles, fat-granules, and crystals of margaric acid. Dèmetre found the colon bacillus and ascribes the fetor to its presence.

The condition may be a grave one, and associated with it may be observed ulceration of the bronchial tubes, with dilatation, pneumonia, abscess, gangrene, and rarely metastatic cerebral abscesses. When *putrefactive changes* take place in the bronchial secretion in the course of chronic bronchitis a new group of symptoms, as a rule, immediately appears. This comprises rigors occurring at irregular intervals and associated with high fever and increased prostration. Cough and pain in the chest also become aggravated, but these acute symptoms may shortly subside and the usual course of chronic bronchitis be resumed. Even under the latter conditions fetor of the breath and sputum may persist.

4. *Dry Catarrh*.—The cough is both severe and paroxysmal, and there is little or no expectoration. When expectoration is present the sputum is very tenacious and is expelled with great difficulty. An asthmatic disposition is sometimes noticeable in this variety, and emphysema is commonly associated. The dry condition of the bronchial mucosa is evidenced by sibilant and sonorous râles. This form occurs in old persons, as a rule.

5. Osler has described a form of chronic bronchitis that occurs most frequently in women, and dates its onset from a comparatively early period of life. It does not undermine the general health. The cough is most pronounced in the morning, and is accompanied by a relatively small amount of muco-purulent expectoration. An examination of the chest yields negative results. The condition seems to proceed from a gouty or tuberculous diathesis in some instances. I have had under observation for several years a young woman in whom this form of bronchitis alternated with eczema of the face.

6. Teichmüller has described an eosinophilic bronchitis. The expectoration is mucoid, as a rule, though occasionally muco-purulent. It is characterized particularly by the presence of a considerable number of eosinophile cells in the sputum. It is not dependent upon adenoid disease of the naso-pharynx. Some writers doubt its existence.

Diagnosis.—The diagnosis of chronic bronchitis is rarely difficult. Since it is usually a secondary condition, it is of the utmost importance to determine the nature of the primary affection. An examination of the heart and of the urine should not be overlooked.

Pulmonary tuberculosis is to be discriminated from chronic bronchitis, and the distinctive points are—(1) A clear tuberculous history. In phthisis there are fever and loss of flesh and strength, while in chronic bronchitis fever is absent and the general health is not impaired. (2) In pulmonary tuberculosis the signs of localized consolidation (usually at one or other apex) appear early, while in chronic bronchitis these are absent. (3) In phthisis the sputum, when examined microscopically, shows the presence of the tubercle bacillus.

In *acute pulmonary tuberculosis* the fever, dyspnea, cyanosis, and increased prostration constitute a group of features that should distinguish it from chronic bronchitis. Coexisting *pulmonary emphysema* is to be recognized by the characteristic symptoms and signs of this complaint. *Primary fetid bronchitis* must be differentiated from the various other conditions previously mentioned, giving fetor of the sputum and breath. In *abscess* of the lung the sputum contains shreds of lung-tissue, including elastic fibers, crystals of hematin, cholesterolin, and

amorphous blood-pigment; usually localized dulness and broncho-cavernous breathing coexist. In *gangrene* there are contained in the sputum shreds of lung-tissue, but separate elastic fibers are often absent, on account of the presence of a ferment that causes a solution of the elastic tissue (v. Jaksch). *Bronchiectasis* is usually unilateral, and gives rise to dulness and other physical signs that are confined to limited areas, while in chronic bronchitis the signs are general.

Prognosis.—Recovery is the exception, though improvement may frequently be observed. The course is exceedingly protracted, and the danger from the late development of certain complications and sequels, such as emphysema or right-sided cardiac disease, must be borne in mind. Since the disease is generally a secondary affection, the prognosis in most instances depends upon the outlook in the primary disease.

Treatment.—The treatment falls naturally under two main heads—(1) Hygienic, and (2) Medicinal.

1. *Hygienic.*—This has reference, frequently, to the removal of various noxious influences. When the patient cannot make a suitable change of air during the cold season, he must keep his room during inclement weather; he should, however, be allowed to spend as much time as possible in the open air during clear and pleasant weather. The vitiated atmosphere of saloons or public halls is to be avoided. The patient should be carefully clad; he should wear flannels next the skin during all seasons of the year, but his outer clothing need not be unusually cumbersome. If the case be of an aggravated type and the circumstances of the patient permit, he should be sent to a warm latitude in the autumn, in order to escape the effects of a severe northern winter. Patients in whom the bronchial secretions are abundant should be sent to a dry, warm climate or to a region whose atmosphere is impregnated with the balsamic vapors of the pine. On the other hand, patients with dry bronchial catarrh are most relieved by an equable, moist, warm climate. Among suitable resorts, those that should be mentioned are the Riviera, Cannes, San Remo, Sicily, and Algiers abroad, and Florida, Southern Georgia, and Southern California at home. Change of air may also become an effective means of prevention.

Prophylaxis also includes the removal of any diseased conditions that are casually related. The coexistence of cardiac disease, the gouty diathesis, obesity, and particularly any renal disturbance, call for the primary treatment of these conditions. Hardening (*Abhärtung*) is an important preventive method, and is accomplished by hydropathic measures—the cold sponge, douche, or plunge—if there be no contraindications.

The *diet* should be generous, but not stimulating, and articles easy of digestion should be selected. Wines and liquors are to be avoided unless particular indications for their use exist. Special conditions, however (*e. g.* albuminuria), may render necessary a special dietary.

2. *Medicinal.*—In this disease medicines are palliative in their effects rather than curative. Relaxing expectorants are to be avoided, owing to their depressing action, and the stimulating expectorants are, in a majority of cases, not only valueless, but hurtful, tending to lessen the appetite and disorder the digestion. When, however, the sputum is muco-purulent and is dislodged with difficulty, expectorants of this class (squills, senega, ammonium muriate) may be tried. I have obtained good results from the use of the following in severe paroxysms of cough:

R_x. Ol. eucalypti, ʒjss–ʒiij (6.0–12.0);
 Codeinæ, gr. vj (0.388).
 M. et ft. capsulæ No. xvij.

Sig. One every four hours, as required.

Occasionally potassium iodid exerts a curative influence, but its use may be limited to cases that are due to the syphilitic, rheumatic, and gouty diatheses. Five or ten grains of the iodid four times daily may be exhibited, and should there be present a syphilitic taint the remedy should be pushed to the limit of tolerance. The balsam of copaiba is sometimes efficacious:

R_x. Balsami copaibæ, ʒj–ʒij (4.0–8.0);
 Ammon. muriat., ʒij (8.0);
 Extr. glycyrrh. pulv., ʒj (4.0).
 Mist. ammoniaci, q. s. ad ʒʒiij (96.0).—M.

Sig. ʒij (8.0) every four hours.

Other remedies that possess great value in certain cases are creasote (in ascending doses), turpentine, terpine, tar, the balsams of tolu and Peru, and sandal-wood. Box¹ advises the emptying of the cavities by the process of inversion—night and morning.

If the vital powers are poor, bitter tonics, as iron, quinin, and strychnin, and other measures calculated to invigorate the system, are indicated. When the sputum is excessive in amount, astringents (zinc sulphate and oxid) are sometimes useful. Astringents may also be used with advantage in the form of a spray when the expectoration is too free. On the other hand, sprays from properly selected solutions (*e. g.* ammonium muriate, gr. v–x ad ʒj—0.324–0.648 ad 32.0) are valuable in assisting expectoration. The patient may inhale the fumes from boiling water containing a few drops of nitric acid for five to ten minutes thrice daily. In fetid bronchitis sprays of antiseptic solutions are to be used, and the following will be found serviceable:

R_x. Phenolis, gr. ij–iv (0.129–0.259);
 Olei eucalypti, ʒij–iv (0.133–0.266);
 Aquæ, ʒj (32.0).

Sig. To be inhaled from a steam- or hand-atomizer.

Pneumato-therapy has given brilliant results in certain instances. After deciding what microorganism is responsible, the corresponding vaccine (autogenous) should be employed. If different organisms be found, the results are unsatisfactory.

BRONCHIECTASIS.

Definition.—The universal or circumscribed dilatation of the bronchial tubes.

Pathology.—Two main forms are recognized—the cylindrical or

¹ *Lancet*, Jan. 5, 1907.

simple, and the saccular, and both of these may be met with in the same lung. Rarely the condition is congenital. It may be general or partial, the former variety being always unilateral, the latter sometimes bilateral. In *universal bronchiectasis* the bronchial tubes, throughout their extent, are the seat of numerous sacculi communicating with one another. These present smooth, shining walls, except in the most dependent parts, where ulcers are sometimes seen. Extreme conditions of dilatation may take the form of huge cysts, which may extend to the periphery of the lung; the lung-tissue lying between the sacculi then becomes cirrhotic as a rule. In *partial dilatation* the bronchial mucous membrane is implicated, with an occasional narrowing of the lumen. Usually these dilatations are cylindrical, though they may be saccular, and rarely fusiform. The partial is the most common variety.

Histology.—When the walls of the larger dilatations are examined microscopically, the cylindrical epithelium is seen to be replaced by a pavement epithelium. The elastic and muscular layers are thin, and the fibers are usually separated. Contained in these dilatations are found secretions that may frequently be fetid.

Etiology.—In the majority of instances the condition doubtless arises from an involvement of the bronchial mucosa that extends to the submucous tissue and leads to muscular, fibrous, and cartilaginous atrophy. These changes render the wall of the tube unable to resist the pressure of the air in violent paroxysms of cough, and, once the process of dilatation is commenced, the accumulated secretions may tend by their weight to distend further the already weakened walls. Thus the elasticity of the latter is impaired, and finally destroyed. The etiologic factors show the affection to be *secondary* as a rule, and are—(1) Chronic bronchitis and emphysema, chronic phthisis (usually when the seat of the dilatation is at the apex), broncho-pneumonia (in children), and compression of a bronchus (*e. g.*, by aneurysm). Heubner believes that bronchiectasis in adults may be sometimes traced to whooping-cough and measles in young children. (2) Great thickening of the pleura, especially when associated with bronchitis or interstitial pneumonia, with contraction of the lung. (3) Rarely it is congenital.

Among predisposing conditions are—(a) *Age*, bronchiectasis being most common in adult or middle life; and (b) *Sex*, being more common in males than females.

Symptoms.—There is always *cough*, usually in prolonged and severe paroxysms. The attacks take place most generally in the morning when the dilated tubes are full, and may be excited by a change of posture. Accompanying the cough there is *profuse expectoration*, which may amount to a pint or more in twenty-four hours. The sputum is grayish-brown in color and muco-purulent, emitting a sour or, more frequently, a horribly *fetid odor*. On standing, the expectoration separates into three strata—the uppermost, of brownish froth; the middle, of a thin, sero-mucous fluid; and a thick sediment, of cells and granular débris. Examined microscopically, the sediment is seen to be composed chiefly of pus-corpuscles, with which are intermingled Charcot-Leyden and fatty-acid crystals, the latter arranged in bundles; leptothrices, vibrios, and bacteria are also found. Elastic fibers may be observed if ulcers be present.

Dyspnea is noted, but is not a prominent symptom, unless some other chronic affections of the chest coexist or some complication arises. *Hemoptysis* occurs rarely, and may be due to the bronchiectatic lesion. Abscess of the brain may develop, though rarely.

Physical Signs.—These differ in character according to the size, situation, and nature of the dilatation, and also according to the condition of the surrounding lung-tissue.

On inspection retraction of the chest-wall may be noted when chronic pleurisy and interstitial pneumonia are associated. The tactile fremitus is usually increased, but may rarely be diminished. The *percussion* resonance is impaired or even flat, and on *auscultation* bronchial breathing is heard, with occasional râles that have a metallic quality. A *saccular dilatation* immediately beneath the pleura may give a tympanitic note, and may also give typical cavernous or amphoric respiration. A tympanitic resonance over a circumscribed area which prior to cough and expectoration presented dullness, is a significant sign (Babcock). These signs are generally discoverable at the base of one or other lung.

Diagnosis.—Simple dilatation of slight degree may exist without appreciable signs, and in other instances the breathing is broncho-vesicular over localized areas, with râles displaying increased metallic quality.

SACULAR BRONCHIECTASIS.

History of chronic bronchitis, chronic pleurisy, and interstitial pneumonia, or of foreign body.

Cough is paroxysmal, and sputum characteristic and copious.

Tubercle bacillus absent.

Course longer, with little impairment of the general health.

PULMONARY TUBERCULOSIS.

History of cough, hemoptysis, with progressive loss of flesh and strength. Family history.

Cough less paroxysmal. Sputum nummular in the stage of cavity.

Tubercle bacillus present.

Course relatively shorter, powers of the system progressively undermined.

Physical Signs.

The condition is persistent, but non-progressive. Usually located at base.

More apt to be progressive, commonly at one or other apex.

Circumscribed empyema with a fistulous connection with the lung may simulate bronchiectasis. There is often in such cases a clear history of an acute illness with a sudden onset, the symptoms pointing to pleural inflammation. The patient suddenly expectorates, at irregular intervals, large quantities of purulent matter. *Actinomycosis* may also cause conditions that simulate bronchiectasis. The diagnosis may be made by finding granular particles containing the actinomyces in the sputum.

Prognosis.—Apart from certain remote dangers (*e. g.* abscess, gangrene, fatal hemorrhage from an aneurysm in the wall of the cavity), these cases pursue a favorable but exceedingly long course.

Treatment.—The lesion being a permanent one, there is no known remedy that will either abridge or influence the course of the affection. Again, since the cough is protracted and attended with profuse expectoration, sedatives and ordinary expectorants are contraindicated. For the fetor, antiseptics are to be employed both topically and internally, and a solution of carbolic acid (1–3 per cent.) or thymol (1:1000) is to be used by inhalation. Internally, terebene (M_{V-X}—0.333–0.666) in capsules every four hours is valuable; also creasote in increasing

doses (m_j —0.066, increasing by m_j each day, till m_{vj} —0.399—are taken three times daily) is to be persistently employed. Intrathoracic injections are often resorted to with gratifying results.

If the dilatation is situated superficially and not amenable to therapeutic measures, it may be freely opened and thoroughly drained. By raising the foot of the bed or lowering the head of the patient in other ways we favor the discharge of the accumulated secretions from the sacculations. Hoppe-Seyler recommends the continuous nocturnal postural method in cases in which no contraindications exist.

BRONCHIAL STENOSIS.

Definition.—Narrowing of the bronchus, due either to constriction or to compression.

Pathology and Etiology.—(a) *Stenosis due to Constriction.*—This form is most frequently occasioned by the presence of foreign bodies; by new growths (polypoid) within the bronchi, or the cicatrices of healed ulcers, and in the smaller bronchi by swelling of the mucosa. The bronchial walls also sometimes become thickened by inflammatory exudates in certain acute and chronic affections; such as syphilis, tuberculosis, and glands.

(b) *Stenosis Due to Compression.*—Compression of one or more bronchi may be met in enlargements involving the thoracic organs, *e. g.*, aneurysm, echinococcus cyst, solid tumors, enlarged glands, mediastinal and pulmonary abscesses, and pleural effusion.

Symptoms.—The symptoms depend upon the size of the bronchus affected and the degree of stenosis. *Dyspnea* is the most conspicuous symptom, but the proper filling of the lungs with air is not accomplished. Under these circumstances the air in the lungs becomes rarefied, and instead of normal expansion everywhere the lower part of the sternum and the lower ribs are *retracted* on inspiration. Obstruction of the primary bronchus on either side of the chest would naturally be followed by inspiratory retraction of the inferior part of the chest-wall and intercostal spaces upon the affected side. The movements of the larynx are slight in bronchial stenosis, while they are marked in laryngeal obstruction. *Cough, expectoration, and fever* are sometimes present.

Physical Signs.—*Inspection* shows defective respiratory movement upon the side involved. The local tactile fremitus is diminished or absent upon the affected side. The *percussion-note* remains unaltered, though less influenced by forced respiration and, particularly, expiration than in health. Pulmonary atelectasis may occur as a secondary event, and is shown by dulness on percussion. The *auscultatory* signs consist of a greatly diminished vesicular murmur on inspiration, due to the diminished amount of air entering the air-cells, and the presence of râles, sibilant and sonorous, at the seat of obstruction. Obstruction of a small

bronchus may, however, be present without appreciable physical signs, owing to collateral emphysema.

Diagnosis.—The nature and site of the affection may be determined by auscultation, and sibilant and sonorous râles will be conspicuous at the point of constriction. A clear history, together with a careful investigation of antecedent affections of the thoracic organs leading up to the stenosis, are factors that must furnish the etiological data in individual cases after the exclusion of foreign bodies as the possible cause. Tracheal or laryngeal stenosis may be eliminated by careful laryngoscopic examination.

Prognosis.—The duration is indefinite, though usually protracted, and most cases yield an unfavorable prognosis. In those instances, however, in which the narrowing is due to foreign bodies the latter may rarely be dislodged and fortunately ejected.

Treatment.—The treatment must be addressed to the cause in individual cases. Obviously, the question of the removal of foreign bodies from the bronchi falls within the domain of surgery, though the administration of an emetic has been followed by complete success in certain instances. Obstruction due to stenosis of a main bronchus may be treated by dilatation with bougies, the treatment of course being carried out by a specialist.

ASTHMA.

(*Bronchial Asthma.*)

Definition.—A chronic affection, characterized by paroxysmal dyspnea, due to contraction of the muscles of the smaller bronchi. The paroxysmal dyspnea produced by arterial contraction is also termed asthma.

Pathology.—In many cases there is hyperemia of the bronchial mucosa, due to pneumogastric or vasomotor functional disturbances, and also a characteristic exudate of mucin. In others there may be no lesions whatsoever, and the condition is a pure neurosis, often of reflex origin. Von Leyden considers asthma to be a reflex neurosis, the *primum movens* of which may be situated almost anywhere in the body. The morbid changes peculiar to chronic bronchitis, pulmonary emphysema, and right ventricular hypertrophy with dilatation are found at autopsy.

Etiology.—There is present either a constitutional peculiarity or a singular susceptibility of the local muscular fibers to spasmodic contraction, both of which are of unknown nature. The exciting factors are very various, but may be grouped under four heads :

(1) **Acute Bronchitis.**—It must not be forgotten, however, that a bronchitis may be set up by the paroxysms. Curschmann has observed also a local croupous inflammation of the smaller bronchioles in some of his cases, which he describes as *bronchiolitis exfoliativa*, and which seems to have given rise to the seizures in grave cases.

(2) The inhalation of numerous and widely various *irritants*, as

chemical vapors, smoke, fog, dust, and emanations from plants or certain animals. A person may be immune in the city and suffer greatly on going into certain rural districts.

(3) *Reflex Causes*.—The causal connection between obstructive affections of the nose and asthma is a subject that is appreciated by the specialist. Gastric disturbances, intestinal irritation, pregnancy, and uterine disorders may cause this complaint. In dyspeptic asthma Boas found the diaphragm elevated above its normal position.

(4) Asthma may be secondary to, and most probably excited by, cardiac disease ("cardiac asthma," due to an acute rise in blood-pressure—Petreu¹), emphysema, gout, rheumatism, syphilis, Bright's disease, emotional excitement, and irritating lesions in the region of the medulla. Possibly, some of the latter affections merely constitute predisposing factors. In this connection it is to be pointed out that individual liability to the disease depends upon the special etiologic factor.

(5) The spasm may be due to some chemical substance or toxin acting on the respiratory center.

Predisposing Causes.—*Heredity* takes first place, and is noted in about 50 per cent. of all cases. The complaint is about twice as frequent in *males* as in *females*, and, if we except hay asthma, it is more prevalent in winter and early spring than during the warm season.

Clinical History.—Hyde Salter's collective statistics show that prodromal symptoms appeared in about one-half the instances (in 111 out of 226 cases). They differ, but are chiefly *nervous* in most cases, and appear as irritability of temper, either depression or unusual buoyancy of spirits, headache, drowsiness, and vertigo. Abundant diuresis and digestive disturbances may be seen.

The *paroxysm* usually comes on in the night during sleep, and at a definite time. It may develop, however, while awake or, rarely, during the day. The onset may be sudden, but perhaps more frequently the patient first experiences a moderate grade of dyspnea and thoracic constriction. This augments with unwonted rapidity, and often attains to an inordinate degree, until the patient feels smothered, sits up, grasps his knees with his hands, or places the palms upon the bed so as to raise the shoulders and thus reinforce the accessory muscles of respiration. When the attack is severe, he rushes to an open window if able to leave his bed, or sits on a chair and places his arms on the back of another chair, so as to fix the shoulders and thus give purchase to the auxiliary muscles of respiration while frantically endeavoring to maintain the act of breathing. The *face* is pale, anxious, and soon bedewed with cold perspiration, while the lips, eyelids, and finger-tips are livid, owing to defective oxygenation of the blood. The *temperature* is subnormal and the *pulse* feeble and rapid. The clinical picture wears an alarming aspect.

Physical Signs.—*Inspection* shows enlargement of the chest, which in the advanced stage becomes barrel-shaped. The reason for this is the presence of an increased amount of air in the thorax with a total inability to expel it. The respirations are diminished in frequency to 12 or 10 per minute. The natural rhythm is also greatly disturbed, and inspiration is seen to be short and gasping, and followed immediately by greatly prolonged expiration. The expansile movement of the chest is

¹ *Berliner klinische Wochenschrift*, Dec. 27, 1909, xlvii, 52.

very limited, and in inverse ratio to the patient's efforts at breathing. There is lowering of the diaphragm. *Palpation* is negative in its practical results. *Percussion* yields a hyper-resonance; in advanced cases with associated emphysema semi-tympanic resonance is common. On *auscultation* inspiration is found to be short and feeble, and expiration much prolonged and accompanied by a low-toned wheezing sound that may also be audible to onlookers. A great variety of dry râles are heard, chiefly high-pitched, sibilant, and sonorous, that are more marked on expiration than inspiration. They also change their character and situation frequently. At the close of the attack moist râles may be heard, and occasionally, when bronchitis complicates asthma, the moist râles may be combined throughout the paroxysms.

The *duration* of the attack is various, ranging from a few minutes to several hours, though rarely it may endure a week or two, with spontaneous remissions during the day (*e. g.* when chronic bronchitis coexists). Usually it subsides *abruptly*, with the expectoration of rounded gelatinous masses and, later still, of muco-purulent material. The former, when floated in water, are found to be composed of the so-called *Curschmann's spirals* (mucous moulds of the smaller tubes), and the spiral character of these small, ball-like pellets may even be detectable with the naked eye. When examined microscopically their spiral structure is evident. Two forms are recognized: (1) Composed of *mucin*, arranged spirally; in its meshes may be observed alveolar cells, many of which have undergone fatty degeneration. (2) A perfectly clear and translucent filament that is most probably composed of transformed mucin and occupies the center of the coiled spiral of mucin. In the early stage of the attack Curschmann's spirals (Fig. 45) are invariably

FIG. 45.—Curschmann's spirals (bronchial spirals).

present in the expectoration, and in many instances Charcot-Leyden octahedral crystals are also visible. The latter are a product of the eosinophile leukocytes and are found also in the semen, in leukemia, and in the stools of patients suffering with intestinal parasites. Müller, Fink, Leyden, and others have demonstrated extremely large numbers of *eosinophile leukocytes* in the sputum. Fink and Gabritchewski have found a large excess (ranging from 15 to 35 per cent.) of eosinophile leukocytes in the blood. V. Noorden and Swerchewski found the same increase, but only at the times of the attacks.

Diagnosis.—A clear history, together with the physical signs and a microscopic examination of the sputum, should lead to correct results. The history alone is inadequate to put the physician upon the right track. *Laryngeal affections*, which give rise to spasm of the glottis and dyspnea, are to be eliminated by the alteration of the voice and the aphonia which are usually present, while the characteristic physical signs of asthma are absent. Again, the dyspnea is inspiratory, not expiratory as in asthma.

Emphysema may be confounded with asthma. The presence of recognized causes, of typical physical signs, and the paroxysmal dyspnea in asthma are the chief points of distinction from emphysema. The sputum should be examined microscopically if doubt remain. The so-called *cardiac asthma* is distinguishable by the presence of indications of chronic nephritis with oncoming failure of the left ventricle.

Course and Prognosis.—In mild cases of asthma there may be but one or two nocturnal paroxysms, with entire freedom from cough and dyspnea during the following day, while in severe ones there is a repetition of the paroxysms from three to five or six nights. Under these circumstances in the intervals (usually corresponding to the period of day) there are slight wheezing and some cough. In long-standing cases asthma leads constantly to the development of chronic bronchitis and emphysema, hence these affections are often combined. The paroxysmal character of the affection is often partly or wholly lost, the patient rarely being entirely free from asthmatic dyspnea, combined with cough and mucopurulent expectoration. The periodicity of the attacks varies; in some it recurs monthly or at shorter intervals, and in others only annually.

There is rarely any danger to life, except when the secondary affection is emphysema, and its remote consequence is dilatation of the right ventricle; but the percentage of cases in which recovery actually takes place is comparatively small, since the affection may reappear long after the paroxysms have ceased to recur in the usual manner.

Treatment.—The indications for treatment are—(1) to cut short the paroxysms and (2) to prevent a recurrence of subsequent attacks.

(1) To bring relief during the paroxysms we should ascertain the exciting cause, and remove it promptly if possible to do so. In one of my own cases a prolonged paroxysm was cut short by a calomel purge followed by an enema. An overloaded stomach calls for an emetic, and other causal factors are sometimes removable (*e. g.*, congestion of the nasal mucosa, dust, vegetable emanations). If the cause is irremovable, the patient should be kept in a freely ventilated apartment, and everything that tends to impede respiration must be removed. The choice of posture as affording the greatest relief may usually be left to the patient.

To cut short the paroxysms: The particular mode of treatment that will afford most speedy relief differs widely in different cases, and not infrequently the patient, as the result of experience, is aware of the most efficacious remedies. As a rule, however, sedative antispasmodics, relaxants, and stimulants are the classes of medicinal agents from which a careful selection is to be made; and while a great variety of these have been employed, I shall content myself by adducing here only the most valuable. In the hands of some observers a few whiffs of chloroform have proved highly efficacious, but in my own they have produced only momentary good effects; ether is the safer remedy and may be tried in like manner.

In a certain proportion of the cases from four to six drops of amyl nitrite thrown upon cotton-wool or a handkerchief, and inhaled, bring speedy and permanent relief. Of stimulants, coffee is the best: immediately upon the appearance of the paroxysm about one pint of strong coffee is to be taken hot (without cream or sugar), and in this way the seizure may sometimes be arrested. Alcohol when given hot and in sufficiently large doses to induce mild intoxication may be found very useful; and with "hot toddy," spirits of chloroform may be combined.

The inhalation of the fumes of niter-paper¹ often gives quick, temporary, and, less frequently, permanent relief. When employed, the atmosphere of the room occupied by the patient must be well filled with the fumes.

Among depressant antispasmodics are belladonna, hyoscyamus, stramonium, and lobelia, and these seem to be of most value when used in the form of cigarets. The leaves of the plant employed are first steeped in a concentrated solution of potassium nitrate or chlorate, and a trial should be made of different sorts of cigarets or pastilles (which are similarly prepared), since all cases are not benefited by the same brand. The inhalation of tobacco-smoke is equally beneficial in rare instances.

A large number of cases, despite the use of the measures above indicated, exhibit an obstinate tendency, and for their treatment no remedy bears favorable comparison with morphin, administered hypodermically. It has occasionally led to the establishment of the morphin-habit; hence it must not be used indiscriminately. It is best given in full doses (gr. $\frac{1}{3}$ — $\frac{1}{2}$ —0.0216—0.0324), and may be combined with atropin. V. Noorden uses atropin in ascending doses (gr. $\frac{1}{120}$ increased to $\frac{1}{16}$ daily), then gradually diminishes the dose; this treatment is repeated every few months, though lessening the dose and shortening each course of treatment. The following formula has proved efficient in my hands:

| | | |
|------------------------------------|--------------|-------------|
| R. Tr. lobeliæ, | ʒj | (4.0); |
| Tr. nitro-glycerini (1 per cent.), | ℥xvj | (1.06); |
| Sodii bromid., | ʒv | (20.0); |
| Vini ipecac., | ʒv | (20.0); |
| Ext. hyoscyami, | gr. viij | (0.518); |
| Elix. simplicis, | q. s. ad ʒiv | (128.0).—M. |

Sig. ʒj (4.0) every one or two hours in water.

S. Solis-Cohen lauds hyoscin hydrobromate (gr. $\frac{1}{200}$) administered hypodermically. Ergot and adrenal extract are among promising remedies; they probably act by promoting vascular tone. Bullowa and Kaplan,² in conformity with the angioparetic theory of an attack, recommend the hypodermic administration of adrenalin chlorid, and claim that it cuts short an attack in from two to ten minutes. The dose is 3 to 6 minims of the 1:1000 solution. Gunzel reports striking results from the high-frequency interrupted current to the vagus, accessorius, phrenic, and sympathetic nerves. In the protracted cases, associated with chronic bronchitis and emphysema, the above mixture may also be employed, though sodium iodid (gr. v—0.324) should be substituted for the bromid, and given at intervals of three or four hours.

(2) In order to prevent subsequent attacks: During the intervals

¹ Niter-paper is prepared by dipping bibulous paper (filter- or blotting-paper) in a solution of saltpeter.

² *Medical News*, October 24, 1903.

the physician must ascertain whether any of the numerous causes (bronchitis, gastric disorders, dust, emanations from plants) are discoverable; if so, efforts to remove them should be instituted. A methodical interrogation of the various organs of the body and their functions must be carried out, and the therapeutic or hygienic indications presented by them, if any, must be met judiciously. The nasal passages should be examined by a specialist, and any causal conditions found therein promptly removed. Rochester¹ emphasizes the importance of "so regulating the intake of food and stimulating the eliminating of waste products, that proper metabolic balance may be maintained." The patient should dine early, so that digestion may be completed before he retires. If the affection be a pure neurosis or due to bronchitis, a suitable climate may often be found in which the patient will enjoy complete immunity from asthma. The choice of the locality cannot, however, be determined by any known rules. The patient must travel from place to place until he finds the climate that possesses preventive properties in his particular case. To those who cannot adopt this plan, potassium iodid offers the best hope of relief, though its use must be long continued (gr. x-xx—0.648-1.296 three times daily). The systematic use of compressed air in the pneumatic cabinet and also the inhalation of oxygen are worthy of trial. In the belief that asthma is a special form of neurasthenia, Treupel aims to regulate the breathing, training the patient to breathe deeply with a slow inspiration, at the same time raising the arms over the head, and then during expiration applying the hands to the front and sides of the chest, squeezing the walls together to aid in expelling the last traces of air. The presence of any condition of ill-health calls for appropriate treatment.

There are also certain means of prophylaxis for impending attacks. Thus, if there be premonitory symptoms, the use of such measures as strong coffee or the "hot toddy," above mentioned, Hoffman's anodyne, stramonium or belladonna cigarets, the inhalation of the fumes of niter-paper or of a few drops of amyl nitrite, or the removal of the sources of irritation, may suffice to ward off the attack.

FIBRINOUS BRONCHITIS.

(*Plastic Bronchitis; Croupous Bronchitis; Mucous Bronchitis.*)

Definition.—A rare acute or chronic catarrhal affection of the bronchial mucosa, attended with the production of fibrinous casts (?) that are expectorated in severe paroxysms of cough and dyspnea. These casts, when unfolded, are found to be molds of the bronchial tubes from which they come, being shaped like the branches of a tree, and thus proving that a bronchial tube and its subdivisions had been blocked.

Pathology.—The pathology is but little understood. When examined microscopically they are seen to consist of a fibrillated base, a few scattered leukocytes and mucous corpuscles, and, rarely, gland- and blood-cells. Curschmann's spirals are often found, and within these or associated with them the Leyden crystals. First, Beschorner and later Grandy have shown the casts to be composed of mucin. In other cases,

¹ *Jour. Amer. Med. Assoc.*, vol. xlvii, Dec. 15, 1906.

however, similar studies show fibrin. In one of my own cases I found the composition of these casts to be identical with that of croupous exudates met with elsewhere, though more dense, perhaps, than the latter. Croupous bronchitis is attended with loss of epithelium in the implicated bronchi, as is the case in croupous inflammation wherever it occurs; but the answers to the questions, "Why should the affection be limited to a definite portion of the bronchial tree?" and "Why does it recur from time to time?" are obscure indeed. In fatal cases the lesions of associated or antecedent complaints, such as chronic pleurisy, pneumonia, and pulmonary tuberculosis, have been found.

Etiology.—What the irritant is that causes the condition is unknown, though streptococci and pneumococci have been found in the molds and in the mucosa. Some of the *predisposing causes* recognized are—(1) *Sex*: it being about twice as frequent in males as in females. (2) *Age*: though met with at all periods of life, it is relatively more frequent from the twentieth to the fortieth year. (3) *Season*: the seizures are most common in the spring months. (4) *Epidemic influences*: Pichini has described a group of instances that occurred in individuals in the same locality. (5) *Hereditary influence* has been traceable in a few cases. (6) *Infective diseases*, such as tuberculosis (quite frequently), pneumonia, influenza, erysipelas, scarlatina, etc., and certain skin affections, as herpes, impetigo, and pemphigus, form antecedent and associated conditions.

Symptoms.—(a) *The acute form* is rare. It begins with rigors and fever, soon followed by urgent dyspnea and severe paroxysms of cough, which are usually attended, soon or late, by the expulsion of bronchial casts, and sometimes rather profuse hemorrhage. Abundant expectoration usually causes amelioration of the severer symptoms. On the other hand, urgent dyspnea, oppressiveness, and severe cough, with little expectoration, are grave symptoms, often leading to fatal asphyxia.

(b) *The Chronic Form.*—The attacks are less severe than in the acute form and recur at irregular intervals, the interim varying from one week to a year or more. In a case observed by myself the patient has experienced a recurrence once annually (on or about May 1st). The paroxysms may occur at regular though much briefer intervals. The cases usually manifest ordinary bronchitic symptoms, with or without fever at the outset. The cough soon becomes troublesome and is paroxysmal. There is expectoration of rounded masses, which, when unravelled, are found to be true moulds of the affected tubes exhibiting a laminated structure. The larger casts (which are of the size of a goose-quill or even larger) may be hollow. They are of whitish or grayish-white color. Hemorrhage may occur.

Physical Signs.—Owing to the obstruction offered by the casts, there is a diminished amount of air entering the corresponding part of the lung. Hence the tactile fremitus, local expansion, and respiratory murmur are diminished over the affected area. The percussion note over the uninvolved portions of the lung is clear or hyper-resonant. The portions of the lung supplied by the affected tubes give impaired percussion-resonance, and if they collapse, there is a dullness on percussion. Dislodgement of the casts is followed by a normal respiratory murmur.

Diagnosis.—The presence of mucous or of fibrinous casts of the finer bronchial tubules serves to distinguish this condition. The fibrinous moulds met with in diphtheria and pseudo-membranous croup, with

extension into the bronchi, must also be eliminated. In doubtful cases a bacteriologic examination of the membranous casts should be made. If the Klebs-Löffler bacilli are then found, its diphtheritic nature is proven. In truly diphtheritic cases the membrane does not present the laminated structure.

Prognosis.—The prognosis in the acute form is quite grave; the chronic variety, though pursuing an exceedingly long course that ranges from five to fifteen years, rarely terminates fatally.

Treatment.—This is to be conducted on the same principles as those in simple acute bronchitis. In the acute form an attempt should be made to soften and separate the casts by the topical application of steam, by inhalation, and alkaline sprays (*e. g.* lime-water). Pilocarpin was employed in one instance under my own observation with apparent good results; it tends to excite free bronchial secretion. Emetics should be resorted to without delay when the signs of cyanosis show themselves.

In the chronic form nothing can be accomplished by treatment, during the intervals between the acute exacerbations, that will tend to obviate a recurrence of the attacks or to mitigate their severity.

IV. DISEASES OF THE LUNGS.

CIRCULATORY DISTURBANCES IN THE LUNGS.

CONGESTION OF THE LUNGS.

(*Hyperemia of the Lungs.*)

Definition.—The surcharge of the pulmonary vessels with blood. Two forms are recognized: (1) Active hyperemia, and (2) Passive hyperemia.

ACTIVE HYPEREMIA.

Pathology.—The blood-vessels in the bronchial mucosa often appear intensely injected, and the capillaries in the alveolar walls are prominent, while on section a scarlet-colored, frothy liquid flows. The alveolar epithelium may become swollen and granular.

Etiology.—Active hyperemia is usually a symptomatic condition, though rarely it may arise as a distinct primary affection. Active congestion of the lungs exists as an associated condition in many pulmonary affections, as pneumonia, pleurisy, bronchitis, and tuberculosis. On the other hand, active congestion of the lungs may be engendered as an independent affection by the inhalation of hot air, highly irritative substances, as well as by violent physical exercise, the ingestion of large amounts of alcohol, and strong mental emotion. Collateral hyperemia may arise from anemia of the opposite lung.

Symptoms.—The capacity of the air-cells is diminished; hence the oxygenation of the blood is markedly interfered with. There is a degree of *dyspnea* proportionate to the extent and intensity of the congestion. There is some fever (101° F.), *cough*, accompanied by *frothy, bloody expectoration*.

The **physical signs** are bilateral, as a rule, and are generally confined

to the bases. *Palpation* shows increased tactile fremitus. The *percussion-note* is impaired or, rarely, dull, and it is generally exceedingly difficult to determine the pitch of the note, owing to the fact that both sides are usually involved. When the condition is unilateral and not associated with diseases of the opposite side, the impairment is readily appreciated. The breath-sounds are broncho-vesicular in character; less frequently bronchial.

Diagnosis.—In the presence of the etiologic factors, the sudden development of *dyspnea*, *cough*, and a *frothy, bloody expectoration*, with the *physical signs* before enumerated render the diagnosis easy. When fever is present it is of a mild grade and short duration.

Prognosis.—Active hyperemia is frequently followed by collateral edema. Its course is brief, and terminates either fatally in a few hours, in perfect recovery in a few days, or in pneumonia. The condition is therefore ominous.

Treatment.—Prompt measures must be instituted in order to arrest the active fluxion. The special causative factors must be actively treated; dry and wet cups over the entire seat of congestion must be tried; and in the worst cases venesection is demanded. Following the application of the cups, turpentine stupes, sinapisms, and linseed poultices may be employed. I have observed excellent results from the use of *veratrum viride* combined with saline purgatives. Other cardiac sedatives may also be employed, including nitroglycerin in full doses.

PASSIVE HYPEREMIA.

Passive, unlike active, hyperemia is always a secondary condition, and is quite common. Two forms are distinguishable: (a) Mechanical, and (b) Hypostatic.

(a) **Mechanical Hyperemia** (*Brown Induration*).—**Pathology.**—The pulmonary vessels are distended, the lungs as a whole enlarged, and the air-cells crepitate but little, owing in great part to the encroachment upon the air-spaces by the dark venous blood. The lungs are of a reddish-brown color and afford increased resistance to efforts at cutting or tearing. On section the reddish-brown tint rapidly changes to a vivid red, from oxidation of the hemoglobin when exposed to the atmosphere. The process commences at the extreme base, extends upward, and may finally become general. The interstitial connective tissue is increased, and is often edematous, while the alveolar cells contain altered blood-pigment, usually in the form of hemosiderin and responding to the usual tests for iron.

Etiology.—Mechanical hyperemia results from the obstruction of the return of blood to the left heart, and among special causative conditions are mitral constriction, mitral regurgitation, dilatation of the right ventricle, and certain cerebral injuries and diseases. It may also be a symptom of asphyxia, and rarely it arises from pressure of tumors.

Symptoms.—The most marked feature is *dyspnea*, particularly when secondary to organic cardiac diseases with failure of the right ventricle. *Cough* is common, and an expectoration of *frothy serum* or *blood* (hemoptysis) containing pigmented alveolar epithelial cells, is the most characteristic clinical feature.

Diagnosis.—With a clear history, in addition to the dyspnea, cough,

and the characteristic expectoration, the recognition of passive hyperemia of the lungs is a simple matter. The prognosis and treatment will be considered in connection with the causative affections.

(b) **Hypostatic Hyperemia.**—**Pathology.**—The parts of the lung that are affected are dark in color and the vesicles distended with a transudate of blood and serum. In this way the air-cells may become emptied of air (*splenization, hypostatic pneumonia*), and the resulting condition is in most instances to be regarded as a mild grade of lobular pneumonia.

Etiology.—Feeble cardiac action, as in long-continued fevers, debilitating chronic affections in old persons, combines with a prolonged dorsal position of the body (gravitation thus favoring its development) in producing the condition. This explains why the condition is found usually at the bases of the lungs, and is most marked posteriorly. It is common for the same reason in carcinoma, tuberculosis, chronic rheumatism, typhoid fever, etc. Hypostatic congestion has followed morphin-poisoning, and is particularly apt to occur in persons suffering from brain lesions, notably those which induce paralysis or coma (Hare).

Symptoms.—The symptoms are wholly indefinite; indeed, none may be present. Priory has pointed out that old persons in the incipency of the disease begin to sleep with the mouth open, so as to effect the entrance of more air. Commencing *cyanosis* may indicate the development of hypostasis, and a careful *physical examination* of the lower lobes of the lungs will show increased fremitus, slight dulness, diminished vesicular murmur, and, in the higher grades, bronchial breathing, with liquid bubbling râles.

The **prognosis** is based upon the character of the underlying affection.

Treatment.—This is an affection in which the treatment of causes alone will suffice, save in instances secondary to organic heart-affections, in which prompt bleedings are to be advocated. From a pint to a quart of blood should be taken, and I have seen happy results from the employment of this measure in extreme cases. Tapping the right auricle when the blood refuses to flow from an arm vein has been successfully accomplished by competent surgeons. The patient's posture must be changed from the dorsal to the lateral, and even ventral, and as soon as possible he should be gotten out of bed.

PULMONARY EDEMA.

(*Edema of the Lungs.*)

Definition.—An effusion of serous fluid into the air-vesicles and interstitial lung-tissue. Pulmonary edema is scarcely to be regarded as an independent affection, but as a secondary condition, being in most instances associated with pulmonary congestion.

Pathology.—It consists of a transudation of serum into the alveolar walls, interstitial connective tissue, and air-cells. Rarely the process is limited to the interstitial tissue. Two forms may, for the sake of convenience, be recognized:

(a) **Collateral Edema** (*Inflammatory Edema*).—This is usually local in character, circumscribing an area of the lung affected by pneumonia, abscess, or pulmonary infarction, and is the result of a mild inflammatory process affecting the vessel-walls. When the condition follows

hypostatic congestion the terms "hypostatic edema" and "splenization" have been applied.

(b) **General Pulmonary Edema.**—If congestion be not associated, the portions of the lungs involved by this type look pale; when pulmonary congestion or pigmentation of the tissue is present, the lung appears darker than the normal and the serum is blood-tinged. The weight of the lung-tissue, owing to the more or less airless condition of the alveoli, is increased, and yet, though heavier than the normal lung, the affected tissue does not sink in water. To the feel it is boggy, and pits on pressure, while on section a serous or sero-sanguinolent (if congestion be present) fluid of low specific gravity, and poorer in albumin than plasma, flows from the cut surface. Edema is most frequently observed at the bases of the lungs, though it may become general. As a rule the surface of the pleura is moist; hydrothorax may be present.

The *mode of production* of pulmonary edema is not definitely known. Increased fluidity of the blood on the one hand, and increased tension in the pulmonary vessels on the other, seem to be influential factors in many cases. The heightened blood-pressure may be in great part due to a failure of cardiac power, and particularly to failure of the left ventricle (Welch). When weakness of the left is out of proportion to the weakness (paralysis) of the right ventricle, the tension in the pulmonary capillaries is apt to be greatly increased, at least until transudation of serum is induced. Edema also occurs as a result of weakness of the right ventricle alone. Obstruction to the outflow, such as occurs in weakening of the left ventricle, or even obstruction in the aorta, leads to heightened tension and, secondarily, to paralysis of the right ventricle. The third factor entering into the production of pulmonary edema is the increased permeability of the vessel-walls, due to impairment of their nutrition and "disturbance of the cardiopulmonic innervation" (Huchard). This usually arises in connection with toxic and infectious diseases, when the blood also exhibits more or less change, as in cachectic states, uremia, general septicemia, and the like. Instances are met with in which pulmonary edema, due to vasomotor relaxation from toxic states, develops suddenly.

Etiology.—Pulmonary edema is secondary to pneumonia and acute and chronic affections, but not with any degree of constancy; nor is it especially liable to be associated with congestion or with low grades of inflammation of the lungs. Among the diseases of which it forms a terminal condition are—valvular affections of the heart, fatal forms of anemia, acute and chronic Bright's disease, cerebral lesions (hemorrhage, traumatism), and acute infectious fevers with failure of cardiac power.

Symptoms.—In edema of the lungs the air-space is lessened in direct proportion to the amount of serum occupying the alveoli; hence *dyspnea* is always present and is often a conspicuous symptom. There are *cough* and *bronchorrhea*. The *sputum* is usually abundant and frothy, and is expectorated with difficulty. At times, and especially in the acute forms, it is tenacious and may give rise to alarming laryngeal obstruction. It is blood-stained if congestion be combined. The condition does not give rise to elevation of temperature, except in the inflammatory type, in which fever is constantly present. The pulse is accelerated and feeble, and cyanosis, particularly in cases of collateral edema, usually appears. The extremities are cool and often livid.

Physical Signs.—The reasons adduced to explain the dyspnea likewise render intelligible the physical signs encountered. There is dulness, though rarely complete, over the areas involved; the vesicular murmur is feeble or absent or there may be broncho-vesicular breathing. Since the bronchioles contain serum, small râles, having a liquid character, are audible with inspiration and at the beginning of expiration over the seat of the edema.

A *recurrent variety* of pulmonary edema has been studied by Crummer, Riesman, and others, coming on without any apparent exciting cause and often proving fatal. "The chief symptoms are agonizing dyspnea, cyanosis, cough, expectoration of frothy, albuminous fluid, and profound prostration" (Riesman). Recovery from an attack is frequent and sudden.

The **diagnosis**, with a clear history, is based upon the incomplete dulness that is usually bilateral and most marked at the bases, upon the bubbling râles heard over the corresponding area, and upon the absence of any febrile movement, except the latter be due to some underlying affection. *Hydrothorax* bears some points of resemblance to edema of the lungs, but in this condition, unlike edema, the upper level of dulness is movable on change of position of the patient. Moist râles, audible in pulmonary edema, are absent in hydrothorax. *Broncho-pneumonia* may be mistaken for pulmonary edema, though it has a different mode of onset. It is also accompanied by fever, glairy, tenacious expectoration, and more sharply localized areas of dulness than appear in edema.

The **prognosis** is governed by the pre-existing condition to which the edema is due. Thus, if secondary to a general dropsy due to renal or cardiac disease, it often destroys life with great rapidity. Inflammatory edema, following lobar pneumonia, is also grave in the extreme.

Treatment.—The treatment is that of the associated or causative affections. These must be sedulously treated, and the limitation of the transudation and the direct removal of the serous effusion from the lungs is of great importance. We should frequently change the position of the patient's body, so as to prevent the gravitation of blood to the dependent portions of the lungs. I have witnessed excellent results from the use of dry cups placed over the thorax, particularly over its posterior and lateral aspects, and renewed at intervals of six to eight hours. The number applied should range from one and a half dozen to three dozen. In aggravated forms that develop quickly prompt venesection is imperatively demanded. This is a measure which, if resorted to at the proper moment, will often rescue the patient from imminent danger. The condition of the heart and kidneys must receive attention. Nitroglycerin is often servicable. Stengel advocates morphin in small doses in the recurrent variety. Tincture of strophanthus (Mij every three hours) is effective in pulmonary edema in children.

HEMOPTYSIS.

(*Broncho-pulmonary Hemorrhage.*)

Definition.—An expectoration of blood. Its source may be the bronchial mucous membrane (usually the small bronchi), and less frequently eroded vessels in lung-cavities or their walls; rarely the larynx, trachea, and larger bronchi. When from the bronchial tubes, the term *bronchorrhagia* should be applied. The source of the hemorrhage, how-

ever, is not always easily demonstrable, even when it has resulted fatally and the lungs are minutely examined.

Pathology.—The lesions are often microscopic, and consist for the most part of ruptured capillary blood-vessels, though larger vessels may also become the seat of erosion or rupture. After death the bronchial mucosa is sometimes found to be swollen, bleeds easily, and is of a dark-red color—soon becoming decidedly pale. The lung-tissue proper may look paler than in the sound lung. In advanced pulmonary tuberculosis the lung-cavity may contain a ruptured aneurysm, or mere ulceration of an exposed vessel may be observed. I have witnessed small, dark-red dense masses in the air-sacs scattered throughout the lung whence came the hemorrhage. Doubtless these are blood-coagula, which result from the clotting of the blood after the latter has been carried into the alveoli. Various associated lesions may be observed.

Etiology.—(1) **Pulmonary Affections.**—(a) *Pulmonary congestion* from whatever source may result in hemoptysis, usually of small amount. There are many causes that excite congestion of the lungs, some of which reside in adjacent organs, it being common in organic disease of the heart, and particularly in disease of the mitral segments. That form of pulmonary congestion which is associated with other affections of the lungs, as well as primary active congestion due to inhalation of hot air, irritating substances, and violent physical exercise, may also result in hemorrhage. (b) *Hemorrhagic infarction* may lead to slight hemorrhage (*vide* Pulmonary Embolism). (c) *Croupous Pneumonia*.—In this disease hemorrhage is caused by rupture of the capillaries, and the blood, when expectorated, has undergone a change and become rusty-colored. (d) *Pulmonary Tuberculosis*.—This is pre-eminently the most common cause. Of 5302 cases analyzed by the writer, hemoptysis was found in 1950, or 36.6 per cent. It is to be recollected that hemorrhages due to tuberculosis are less apt to take place in higher altitudes than at sea-level; but, as pointed out by Bonney,¹ they are decidedly more severe and associated with more shock when they occur. Hemorrhage may take place early when it originates from a sharply limited and minute tuberculous focus, and it may also be attributable to congestion. Undoubtedly its exact source is the mucosa of the small bronchi; later it is the direct consequence of the ulceration of an artery or of the rupture of an aneurysmal sac that has its seat in a branch of the pulmonary artery. After the tuberculous cavities have healed, calcareous masses are, from time to time, expectorated, together with more or less blood. (e) *Ulcers of the Larynx, Trachea, or Bronchi*.—Rarely, ulcers in adjacent structures erode the larger branches of the pulmonary artery and cause copious and speedily fatal hemorrhages. Osler observed a fatal hemorrhage in a case of chronic bronchitis with emphysema. (f) *Fibrinous bronchitis* induces hemoptysis by rupturing the capillaries in the bronchial mucosa at the time of separation of the bronchial casts. (g) *Carcinoma of the lung* produces frequent expectoration of blood. (h) *Gangrene and abscess of the lung*.

(2) **Diseases of Other Organs than the Lung.**—(a) *Affections of the heart* act as a cause, and especially advanced mitral disease with pulmonary congestion. It not infrequently develops during the stage of adequate compensation. In a preponderating proportion of the latter instances the hemorrhage is slight, but it may be profuse and recur at

¹ *Pulmonary Tuberculosis and its Complications*, p. 130.

intervals for many years. (b) *Aneurysm* of the branches of the *pulmonary* artery and of the arch of the *aorta* (usually with rupture of its coats) is a rare cause of *hemoptysis*.

(3) **Certain diseases**, such as *purpura hæmorrhagica*, *scurvy*, *anemia*, *hemophilia*, and *malignant forms of certain acute infectious diseases* (e. g. *yellow fever*), cause *hemoptysis*. In this class of cases the *hemorrhages* are due either to a diseased condition of the vessel-walls or to *blood-changes*.

(4) **Vicarious hemoptysis** is not uncommon during *menstruation* or when *amenorrhea* is present. Unless occurring at the time of the regular *menses* it is not to be regarded lightly, and is of the same significance as when taking place in the male.

(5) **Arthritic (Gouty) Endarteritis**.—According to Sir Andrew Clarke this is a common cause of recurring *hemorrhages* in aged persons.

Symptoms.—*Hemoptysis* is so commonly a symptom of that most frequent and dread disease, *phthisis*, as to raise suspicions of the latter in the minds of the laity and physicians as soon as it occurs. It is appropriate, therefore, to note, first, the features of *hemoptysis* when dependent upon *pulmonary tuberculosis*, and then to point out its clinical peculiarities when due to other conditions.

In *incipient pulmonary tuberculosis* *hemoptysis* develops suddenly as a rule, a *warm, saline taste*, lasting but a few moments, generally preceding the expectoration of blood. The blood is *coughed up*, and the bleeding may last only a few minutes or may continue for days, the *sputum* being apt to remain blood-stained for a longer period. The immediate effect of the *hemorrhage*, however slight, is to alarm the patient, inducing, besides mental agitation, cardiac palpitation and other nervous concomitants. A small *hemorrhage* is not attended with any other results, but large ones give rise to the symptoms of *shock*, combined with those of *symptomatic anemia*. When the *hemorrhage* is large, blood to the amount of a mouthful may be ejected with each cough, and in these instances the effect of the profuse bleeding is evidenced by such symptoms as *vertigo*, *syncope*, cold extremities, excessive pallor, perspiration, and a rapid, small, feeble pulse. This is followed, if the attack does not prove speedily fatal, by considerable restlessness, and later not infrequently by mild delirium and more or less fever.

In comparatively rare instances the same patient has a single *hemorrhage*; more frequently he has several at shorter or longer intervals. Large or small bleedings may precede by weeks, months, or even years any rational symptoms or physical signs of *pulmonary tuberculosis*. In such instances the pre-existence of latent foci of disease may be assumed.

In *quantity* the *hemorrhage* varies greatly, ranging from less than an ounce to a pint or more. In advanced cases in which cavities have formed large vessels may become eroded, followed by copious and dangerous *hemorrhage*. Fatal *hemorrhage* may take place into a cavity without the occurrence of *hemoptysis*, as in a case dissected by Osler at the Philadelphia Hospital. The distinctive characters of the blood discharged are mainly as follows: *bright color*, very *frothy* (being mixed with air), and *not clotted*. In the case of *hemorrhage* proceeding from a large cavity, the blood may, rarely, pour forth in a free, dark stream.

Physical Signs.—These are, for the most part, negative. Quite commonly moist bronchial râles are audible on auscultation; palpation and percussion should not be practised either during or immediately after the hemoptysis.

Hemoptysis Not Due to Pulmonary Tuberculosis.—(a) In *affections of the mitral and aortic valves*, especially in mitral stenosis, hemorrhage from the bronchi is not uncommon, and the way in which these lesions lead to pulmonary congestion (*vide* discussion of Organic Affections of the Heart). During the progress of these cases, hemorrhages often occur at considerable intervals; they may either be slight, lasting only a few minutes, or quite free, extending over periods of a few days or a week.

(b) As a rule, in the beginning small hemorrhages occur for several weeks from pressure of an *aneurysmal dilatation* upon the bronchial mucosa, or there may be weeping of blood through the exposed layers of fibrin composing the walls of the sac. The bleeding point can be discovered with the laryngoscope, when an aneurysm of the innominate or of the aorta impinges upon the trachea. A large and often quickly fatal hemorrhage occurs from rupture into the respiratory tract.

(c) "*Arthritic hemoptysis*" is undoubtedly associated with gouty, degenerative changes in the terminal blood-vessels of the lung, though no coarse pulmonary lesions are induced by the recurring hemorrhages. Although the hemorrhages may occur at intervals for years, as a rule they finally become arrested, and only rarely lead to a fatal issue. I have never observed this form of hemoptysis occurring independently of *chronic bronchitis*. In *emphysema* and *chronic bronchitis* small hemorrhages may occur, and occasionally coagula in the form of casts are formed in the bronchi and afterward ejected. It is probable that the source of the large bleedings is an *ulcer* in the bronchial mucosa.

(d) The hemoptysis that is connected with the *menstrual function* is of frequent occurrence. I saw recently a patient in whom free bleeding has occurred at intervals of four weeks for a couple of years, with an absence of the menses. In another instance, a patient of Dr. Byers, recurring hemorrhages of the lungs took place instead of the regular menstrual discharge for three successive months, and a comparatively rapid and fatal form of phthisis was developed. This case typifies a large class that is especially prone to develop pulmonary tuberculosis.

(e) The preceding group is to be distinguished from those cases in which *trivial bronchial hemorrhages* sometimes occur, and in delicate, hysterical females. Although these bleedings are accompanied by cough, it is not uncommon to find, upon careful examination, that the blood comes from the upper air-passages.

(f) Hemoptysis may result from *severe injuries* inflicted upon the thorax, and last for days.

(g) A person may have a single or many recurring attacks of hemoptysis *without assignable cause*, if we except severe muscular strain or intense mental excitement. Although pulmonary tuberculosis does not supervene in instances of this sort, yet not a few may be excited by a permanently limited tuberculous focus which may be indeterminable by the usual methods of examination. I have more than once seen a cure result from an active course of treatment with creosote and appropriate hygienic measures. In well-marked instances of the kind a complete arrest of the trouble resulted from a change of climate

(h) *Parasitic hemoptysis* due to *paragonimus Westermanii*. The sputum resembles that of lobar pneumonia with intermittent hemoptysis.

Differential Diagnosis.—A reliable diagnosis necessitates the exclusion of hemorrhage from the higher air-passages, pharynx, esophagus, and stomach. In *epistaxis* the blood may directly enter the nasopharynx, excite cough, and be discharged as in hemoptysis. An examination of the nasal chambers should be made when epistaxis is suspected. Bleeding may take place from the gums, from chinks in the pharynx, or from varicose veins. If the seat of the bleeding be the *pharynx*, the hemorrhage is not free, the blood being commingled with a preponderating proportion of mucus; if from the gums, it may be more copious (as in *ptyalism* or *scurvy*). An inspection of the mouth will decide the question. Strümpell distinguishes hysteric hemoptysis by the smaller bleedings, the absence of pus-elements, and the large amount of squamous epithelium, *leptothrix*, and the food-remnants present.

Hemoptysis must be distinguished from *hematemesis* (q. v.).

Prognosis.—The gravest apprehensions are constantly entertained by sufferers from hemoptysis, but immediately fatal results are of rare occurrence; and of this fact the patient should be repeatedly assured by the attending physician. In case, however, of thoracic aneurysm the consequences of hemoptysis are fatal. With reference to the effect of hemoptysis upon tuberculous pulmonary disease, opinions differ widely. Prior to the existence of cavities it often exerts a favorable influence upon the disease. On the other hand, if cavities exist, an opposite effect is observed. The fact that hemoptysis often precedes by prolonged intervals of time the development of pulmonary lesions is no argument in favor of Niemeyer's view, that phthisis is caused by hemoptysis. Some blood, however, finds its way into the bronchi below the point of bleeding and into the air-cells, causing at times irritation and even lobular inflammation. Thus hemorrhages may aid in rendering the tissues susceptible to tuberculous infection. In cases of profuse hemorrhage, due to the erosion of large branches of the pulmonary artery in phthisical cavities, death may be suddenly induced, and is caused largely by inundation of the lung and the consequent impossibility of respiration. Fatal hemorrhages are less common in the female than in the male sex.¹

Treatment.—Since the hemorrhage is ascribable to (1) congestion of the bronchial mucosa, (2) erosion of the vascular walls, and (3) blood-changes, obviously the treatment of individual cases must be modified according to the character of the causative condition.

In many instances of *hemoptysis due to congestion of the bronchial mucosa* the hemorrhages are, comparatively speaking, slight; hence, apart from keeping the patient at absolute rest, little treatment is required. If free, the physician's aim should be to decrease the force of the heart's contraction, and to accomplish this end the patient should be placed in bed, and not allowed to change his position nor to speak above a whisper. The affected side of the chest may be strapped with adhesive plaster. The diet should be light, nutritious, and non-stimulating, all hot drinks and alcoholics being prohibited. Among cardiac sedatives employed with a view to reducing the rapidity of the heart's action and lowering the blood-pressure are the ice-bag to the precordia, and aconite

¹ *Trans. Amer. Climat. Assoc.*, 1909, xxv., 27, by the writer.

and other arterial sedatives internally. Arthur Foxwell¹ recommends venesection in cases in which *venous congestion* is present, and also lays stress upon measures that confine the blood to the systemic circulation—*i. e.*, nutritious food, large doses of the nitrites, hot foot-baths, leeches to the anus, and ligatures applied to the thighs and arms. Brown, Otis, and others advise that the blood-pressure be frequently observed, and if found to be high, nitrite of sodium or nitroglycerin should be employed, or, if low, ergot or ergotine subcutaneously (Otis). The pulmonary capillaries may also be effectually depleted by the use of salines. I have found dry cupping over the chest of the greatest service in cases dependent upon congestion. Eating ice and partaking freely of iced drinks are also useful measures. If the attack tends to become prolonged and exhausting, we may increase the coagulability of the blood by the use of gallic acid, acetate of lead, sodium chlorid, or calcium chlorid. Hemoptysis is usually accompanied by *cough* that constantly disturbs the vascular serenity and excites fresh bleeding; it demands opium or morphin (hypodermically). In blood-spitting due to the gouty diathesis Mays recommends the salicylate of sodium. Amyl nitrite in doses of from 3 to 9 minims often promptly arrests the bleeding by causing an immediate fall in blood-pressure at the bleeding points, "thus giving time for clotting to take place" (Calvert). Fish² reports excellent results from the use of chloroform in 19 cases; he gives from two to four c.c. by inhalation. Subsequently the inhalation of 15 to 20 drops every hour is continued for a few days.

When hemoptysis is associated with *organic disease of the heart*, the main indication is to strengthen that organ by bodily rest and quiet and by the use of cardiac tonics, especially digitalis. I have had under observation for several years a young physician who has been suffering from frequent, marked hemoptysis, due to mitral regurgitation, and in whose case the bleedings are readily controlled by the free use of digitalis.

When in *thoracic aneurysm* or *advanced pulmonary tuberculosis* the blood is ejected in mouthfuls, we may safely infer that erosion of a vessel or rupture of the aneurysm has taken place. Here the object is to bring about the formation of a thrombus that will arrest the hemorrhage. Perfect quiet in the horizontal position tends to allay the vascular excitement, and the induction of fainting by venesection is a measure worthy of a trial. Opium is contra-indicated in the latter class of cases, since if cough be checked inundation of the bronchial system with the blood (the chief danger) will be favored. R. H. Babcock gives an immediate injection of atropin sulphate (gr. $\frac{1}{50}$ — $\frac{1}{25}$) when hemorrhage occurs from a cavity.

In all instances of hemoptysis treatment should not end with cessation of the hemorrhage. A tendency to recurrence is manifested in many cases, and hence measures calculated to avoid this event must be brought into play. The patient should not be allowed to indulge in a stimulating diet; he should eschew tobacco and alcoholic stimulants, and avoid all physical and mental strain. Every source of bronchial irritation should be carefully avoided, and attacks of bronchitis, however mild, should receive the most careful attention. A climate far removed from the seaside is best. Moderate exercise is serviceable, as well as a liberal amount of nutritious food.

PNEUMORRHAGIA.

(Pulmonary Apoplexy.)

Definition.—An escape of blood into the air-cells and interstitial tissue, with or without laceration of the pulmonary parenchyma.

Pathology.—It may be, though rarely, (*a*) diffuse, when the lung-tissue is lacerated, as in cerebral apoplexy; or (*b*) circumscribed, as when the blood is effused into the air-cells and the interstitial tissue, without rupture of the parenchyma. (See Pulmonary Infarction, *infra*.)

Etiology.—*Diffuse pulmonary apoplexy* is caused by the rupture of a thoracic aneurysm that has become adherent to the surface of the lung. Its most common cause is traumatism, especially penetrating wounds, but adult life and the male sex are to be regarded as predisposing factors. Septico-pyemia and cerebral disease are causes.

Symptoms.—These are ill-defined. *Profuse hemoptysis*, *urgent dyspnea*, and *cyanosis*, followed by increasing evidences of *collapse*, together with a clear history, should raise suspicions of the existence of diffuse pneumorrhagia.

The *physical signs* are indicative of extensive consolidation arising suddenly, but not of the nature of the lesion.

The **prognosis** is practically hopeless, and abscess or gangrene may result if these cases recover from the immediate effects of the hemorrhage.

Treatment.—Absolute rest of the body in the horizontal position is the one measure that offers a slight prospect of alleviation, for thus the formation of a clot, followed by arrest of the hemorrhage, is encouraged. It is unwise to use opium to allay the cough, since the action involved assists in ejecting the extravasated blood, which will, in consequence of gravitation and the effect of respiration, submerge speedily so much of the lung-tissue as to hasten the fatal termination. Ergot is contraindicated, but the internal and external use of cold has been highly recommended. With the onset of collapse cardiac stimulants become absolutely necessary, though many cases are so rapidly progressive as to reach a moribund state before remedial agents can be applied by the physician.

PULMONARY EMBOLISM.

(Hemorrhagic Infarction; Embolism of the Lungs.)

Pathology.—Embotic infarctions are firm, airless, brown or black, wedge-shaped masses, with their bases usually at the pleura, which soon becomes lustreless and covered with fibrin. The infarctions may be single or multiple, and may occupy the greater portion of the lobe; in most cases, however, their size equals that of a walnut. Their most frequent seat is at the back of the lower lobe. The microscope shows the presence of leukocytes and red blood-corpuscles in the air-cells and in the alveolar septa. Collateral congestion and edema are frequent concomitants, and, rarely, pneumonic consolidation.

Etiology.—The condition is produced by the blocking of the pulmonary arteries by an embolus or thrombus. When the circulation in the pulmonary capillaries is feeble, hemorrhagic infarction may be the result of stasis, and this is probably the most frequent form. It is met in diseases of the lungs and also in mitral affections. The plug that

occludes the blood-vessel may be composed of leukocytes, as in leukemia, and the chief sources of the emboli are the thrombi in the right heart, in consequence of dilatation, and in the systemic veins. Infectious emboli, resulting in abscesses, occur (*vide* Abscess of the Lungs). An embolism of placental cells in cases of eclampsia has been described. Occlusion of a branch of the pulmonary artery cuts off completely the circulation to the territory supplied by that branch, and hemorrhagic infarction occurs—venous extravasation, with expression of air.

Symptoms.—Not all infarctions give rise to symptoms; on the contrary, occlusion of a main branch of the pulmonary artery usually terminates life speedily. The latter accident occurs not infrequently in connection with organic disease of the heart, and if death be not the immediate result or if a narrower branch be occluded, alarming symptoms ensue, such as *syncope*, *dyspnea*, *pain in the side*, and *convulsions* with *unconsciousness*. The first and most distressing symptom is dyspnea, attended by frantic efforts at breathing and by great mental anxiety. Occasionally *hemoptysis* is an early symptom, and of primary significance if it occur in a patient suffering from mitral disease. *Cough* usually supervenes, accompanied by the expectoration of dark, gelatinous, mucoid masses. Large lymph-cells containing blood-corpuscles are found in the sputum, most commonly in instances of organic cardiac affections.

The physical signs may either be negative—as, for example, when the infarctions are small or deeply located—or they may give information as to the seat and extent of the affected part. When present they are those of sharply-localized consolidation (increased fremitus, percussion-dulness, moist râles, bronchial or broncho-vesicular breathing). It is not improbable that in many cases the physical signs are due, in great part, to associated conditions, such as bronchitis, edema, or collateral consolidation. The appearance of the friction-sound in the course of suspected cases is a great aid in diagnosis. The *heart's action* becomes enfeebled, the *pulse* is small and frequent, and the surface of the body is cool and frequently bedewed with cold sweat. *Fever* may either be present at the onset or absent throughout. The signs of embolic abscesses in the lungs will be elsewhere detailed (*vide* Pulmonary Abscess).

Diagnosis.—To establish the diagnosis of pulmonary embolism there must be a clear history of some etiologic condition, and the sudden appearance of such symptoms as dyspnea, cough, bloody expectoration (in particular), chest-pain, loss of consciousness, and convulsions, corroborated by the physical signs of a sharply-defined spot or spots of consolidation.

Prognosis.—The prognosis differs with the character of the primary condition. On the whole, it is exceedingly grave, though the absorption of an embolism, followed by the disappearance of the urgent symptoms, is not impossible. In case death does not occur soon, infarcts may give rise to abscess or gangrene, due either to bacteria in an original embolus or to their entrance through the air-passages. In other cases an infarct may undergo fibroid change and contraction, and may even calcify.

Treatment.—Beyond procuring absolute rest of the body and a relief from the distressing symptoms, the treatment should be aimed at the affections on which this form of embolism depends. Dyspnea and pain may require the hypodermic use of atropin and morphin, preferably in combination. Heroin relieved the dyspnea in one of my cases.

CHRONIC INTERSTITIAL PNEUMONIA.

(Fibroid Induration ; Cirrhosis of the Lung.)

Definition.—A chronic inflammation of the lungs, characterized by the formation of fibrous or connective tissue. It may occur as a primary or as a secondary affection.

Pathology.—Two leading forms may be recognized: (a) *Local*, and (b) *Diffuse*, though these do not demand separate description. It is a unilateral affection, and the lung of the side involved is much shrunken, its dimensions in some cases being incredibly small. It lies tightly against the spine, and has frequently been overlooked. The heart occupies the affected side, being drawn in that direction during the progress of the disease, and it is enlarged, principally owing to hypertrophy of the right ventricle. The pulmonary artery is the seat of atheromatous change. The other lung is overdistended (*compensatory emphysema*) and may encroach upon the mediastinum. Intrapleural and pleuro-pericardial adhesions may be exceedingly firm and thick or only moderately so, and rarely the pleuræ are intact. The cut surface of the affected lung is hard, dry, airless, shiny, and usually light gray in color (rarely reddish-yellow), and the lung-tissue cuts with great resistance. The blood-vessels and bronchi may be observed gaping in the cut section. Cavities may be due to bronchiectasis or to the superaddition of a tuberculous process. Phthisical cavities may often be discriminated by their usual situation at the extreme apex. The lung that is unaffected by the fibroid process is also quite often the seat of tuberculous change.

Etiology.—The disease is almost invariably secondary, and very generally accompanies prolonged inflammatory and chiefly local changes in the lungs. It may also follow acute inflammatory processes. Examples of **localized interstitial pneumonia** are seen in connection with pulmonary tuberculosis, emphysema, syphilis, hydatids, and fibroid induration secondary to thickening of the pleura.

Diffuse interstitial pneumonia has a variety of causes: (a) It may follow *acute lobar pneumonia* in cases in which resolution is delayed, and here the fibrinous exudate filling the air-cells becomes organized into connective tissue. Fibrous tissue is also substituted for the alveolar walls. The condition is exceedingly rare.

(b) Pneumonia, appearing as a complication in influenza, is very liable to produce chronic interstitial pneumonia.

(c) The disease may also result from atelectasis due to compression, as by aneurysms or neoplasms.

(d) It most frequently, however, follows *broncho-pneumonia* of either acute or subacute form (Charcot). The process starts in the bronchi and extends to the surrounding lung-tissue, till finally an entire lobe, or even an entire lung, may become involved. Tuberculous broncho-pneumonia also leads to the production of new fibrous tissue, but here the process is a conservative one (*vide* Pulmonary Tuberculosis), and hence is not to be classed with chronic interstitial pneumonia.

(e) The initial lesions may be located in the adherent *pleura*, with secondary involvement of the lung, connective-tissue bands ex-

tending into its substance. The bronchi are inflamed and sometimes dilated.

Chronic interstitial pneumonia may, however, exist without implication of the pleura, and in view of this fact the primacy of pleural thickenings cannot be granted without reserve when they form a part of the lesions of fibroid induration.

The various forms of the disease thus far described arise *secondarily*. It may also occasionally originate as a *primary* affection (1) from the inhalation of different forms of dust (*vide* Pneumonokoniosis). (2) Delafield describes "a special form of lobar pneumonia." He contends that lobar pneumonia terminates only in resolution or in death, and that this special disease, with its production of newly-formed connective tissue, is a distinct form of inflammation. The variety described by Delafield runs a subacute or even chronic course, and terminates by crisis. It is an exudative inflammation, with the formation of new tissue from the onset. The consolidated areas are not so large as in ordinary pneumonia, and sections lack the granular character of the latter.

Symptoms.—The patient suffers from *cough*, which increases in intensity with the progress of the affection. There is a mucous, sero-mucous, or rarely bloody expectoration; *dyspnea* occurs early, and frequently is present only on ascending heights; uneasiness, or even *pain*, over the side of the chest involved may be experienced. In cases in which the bronchi become dilated the characteristic symptoms of bronchiectasis are superinduced. The *general symptoms* consist merely in a loss of flesh and of strength. *Fever* is altogether absent.

Physical Signs.—*Inspection.*—The chest-wall of the affected side is retracted, while the healthy lung is enlarged (*compensatory emphysema*). The spinal column is curved laterally. The affected side is fixed during respiration, and the heart is displaced by traction toward the affected side. If the left lung be involved, the apex-beat will be displaced to the left and slightly upward; if the right, the apex-beat will be observed to the right of its normal position. The ribs approximate, thus obliterating the interspaces, and the shoulder droops over the shrunken chest-wall.

Palpation.—The tactile fremitus is usually increased; if the pleura be much implicated or thickened, however, fremitus may be decreased. Palpation discovers no expansile motion.

Percussion.—The percussion-note varies. Dulness is common, owing to consolidation of the lung, but flatness is sometimes met with, and a tympanic or amphoric note is occasionally elicited over a dilated bronchus.

Auscultation.—The breathing is bronchial or more or less sonorous as a rule, and over bronchiectatic cavities it is cavernous or, rarely, amphoric. Near the base it is frequently feeble, distant, or even altogether suppressed. Subcrepitant, sonorous, sibilant, or gurgling râles may be audible, and dry, creaking, or leathery friction-sounds may also be heard.

Prognosis.—The course of the complaint is exceedingly chronic, lasting over many years. Death may result from an intercurrent attack of acute pneumonia affecting the other lung. The disease always shortens life, and may be the direct cause of death. Rarely a fatal issue is due to dilatation of the right heart, followed by tricuspid regurgitation.

Treatment.—The condition is incurable. The patient should, however, be placed under the best sanitary conditions, and if practicable he

should make a permanent change of climate. A suitable resort should be selected in accordance with the rules indicated in the treatment of Pulmonary Tuberculosis, and every effort should be put forth to improve the general nutrition of the patient. Due attention should be given to the associated bronchitis, as well as to any symptoms that may arise during acute exacerbations.

BRONCHO-PNEUMONIA.

(*Capillary Bronchitis; Catarrhal Pneumonia.*)

Definition.—An inflammation of the minute bronchi and air-vesicles, due either to the extension of inflammation from the capillary bronchi to the air-vesicles or to an inflammatory process set up in atelectatic lobules.

Pathology.—*Macroscopically*, the lungs present decided variations in persons who have died of broncho-pneumonia. On the pleural surface may be noticed purplish or slaty patches, often sunken (atelectasis), intermingled with the more elevated patches of healthy lung and grayish consolidation, and smoother and more moist than croupous pneumonia. Similar appearances are presented by the cut surface. On pressure fluid exudes—edematous from the healthier areas, and grayish and puriform from the consolidated areas. The mucosa of the large bronchi may look natural, though frequently it is congested, while the small bronchi usually contain more or less muco-purulent material. Their walls are greatly thickened, and on section the cut surface presents a nodular appearance. Dilatation of the smaller bronchi may be observed, and minute consolidated areas, varying in size from that of a pin's head to that of a pea, may be seen surrounding the thickened walls of the bronchi. When, as frequently happens, they become confluent, large areas—an entire lobe and even an entire lung—of lung-tissue may become consolidated. The solidified zones are firm to the touch, being destitute of air, and at first they contain blood; hence their color is a dark red, later turning to a grayish hue. The condition is usually bilateral. As a rule the bronchial glands are swollen and inflamed. In the non-consolidated portions of the lung the air-cells are considerably dilated.

The essential lesion is a productive inflammation of the bronchi and of the immediately surrounding air-spaces. The inflammation is from the first not exudative, but productive; that is, with the formation of new tissue (Delafield). This form of inflammation may merge into sclerosis of the lung or chronic thickening of the pleura. *Microscopically*, the walls of the bronchioles and alveolar passages are seen swollen and infiltrated with cells; they likewise contain plugs of mucous exudate, most marked near the centre of the process. The air-cells toward the periphery show much less exudate. The latter consists of serum, some mucus, and many swollen cells from the alveoli

(soon showing fatty degeneration), leukocytes, and also red blood-cells in small numbers. Fibrin is seen in small quantity if at all.

In deglutition- and aspiration-pneumonia the leukocytes are present in much larger numbers, and the exudate tends to suppuration, while in the hemorrhagic forms the red blood-cells are relatively increased.

Among the associated lesions to be mentioned are—(a) Catarrhal inflammation of the mucous membrane of the bronchi; and (b) Exudative inflammation of the air-cells, which become filled with epithelium, fibrin, and pus, with resulting consolidation of the lung. The epithelial cells lining the air-sacs, since they are more numerous in young children than in adults, form a larger part of the inflammatory exudate in the former than in the latter. (c) The pulmonary pleura is often coated with fibrin, but less regularly than in croupous pneumonia.

Etiology.—(1) A marked predisposing influence is *age*, the disease being most prevalent amongst young children. In them it may appear in association with measles, whooping-cough, scarlet fever, and diphtheria, but not infrequently it is entirely independent of these diseases. Infants are especially susceptible to the affection, most instances of pneumonia at this period of life being of the lobular form. Other conditions that act as predisposing factors in children are improper exposure to cold, unsanitary surroundings (especially impure air), rickets, and chronic diarrhea. Broncho-pneumonia is also frequent in the aged, often being occasioned by certain debilitating causes and chronic diseases that are common to advancing years (emphysema, gout, chronic valvulitis).

(2) *Season.*—The affection prevails especially in the winter and spring months; particularly is this the case in those forms that are unassociated with the acute infectious group of diseases.

(3) It also supervenes as a complication in such acute infectious diseases as influenza, typhoid fever, erysipelas, and small-pox, and is of serious import. According to my own observations, it is more commonly met with in the diseases above mentioned than is lobar pneumonia.

(4) The *inhalation of food-particles and other substances* often serves to convey the agents of inflammation to the lobules of the lungs. A long-continued recumbent posture predisposes the patient to broncho-pneumonia. It is, however, in conditions in which the larynx and bronchi have totally or in part lost their sensitiveness—as in coma due to apoplexy, uremia, and allied cerebral states—that retention of bronchial secretions occurs, and that, owing to gravitation, these secretions reach the minute bronchi. Pneumonia is similarly produced when we cut the vagus nerves, the paralyzed structures permitting irritants to be carried to the lung by inspiration. *Inhalation pneumonia* may follow operations upon the nose, mouth, larynx (tracheotomy particularly), and is often secondary to carcinoma of the larynx and esophagus. It is also the pneumonia of new-born children.

(5) It must not be forgotten that quite commonly broncho-pneumonia is caused by the *tubercle bacillus* (*vide* Pulmonary Tuberculosis).

Bacteriology.—Weichselbaum has shown the presence of streptococci with the greatest frequency in the usual, secondary form. The pneumococcus is often found, and in a goodly number of cases the staphylococcus aureus (Neumann), while in influenza the specific organism may itself cause broncho-pneumonia (Pfeiffer). Numerous other

organisms have been found (typhoid bacillus, bacillus coli communis). Mixed infection with the *Diplococcus pneumoniae* is almost the rule when lobular pneumonia is secondary to the acute infections.

Symptoms.—Two clinical forms may be distinguished:

(a) **Primary broncho-pneumonia**, which occurs in 30 to 35 per cent. of all cases, is met with generally in children, and presents, in great part, the symptoms of an acute bronchitis of severe grade (*cough, dyspnea, pain, fever*). When occurring in weakly subjects the onset may be gradual. The cough is attended with *expectoration* (glairy and tenacious), that may be blood-tinged, in the form of droplets or points. The fever is moderate, the temperature ranging from 101° to 104° F. (38.3°–40° C.), and is of irregular type; in severe cases, however, continued high temperature may occur. Physical examination gives the same result as in the secondary form. The *duration* is from two to four weeks, the fever terminating by *lysis*. West holds that primary broncho-pneumonia in children is of pneumococcic origin.

(b) **Secondary broncho-pneumonia** is the variety usually met with. The symptoms are frequently veiled by those of the primary affection, and, indeed, a moderate grade of lobular pneumonia is frequently unsuspected during life when arising in the course of other grave diseases.

It is usually preceded by bronchitis affecting the larger bronchi, and in this common event the first symptom that directs attention to the disease is the *sudden increase* in the frequency of the *respirations*, which rise as high as 60 or even 80 per minute. An initial chill is rare. *Fever* develops suddenly, or, if previously present, increases rapidly. An early symptom is the *cough*, which is usually hard, harassing, frequently painful, and accompanied by *expectoration*. The *pulse* is frequent, and in the later stages may be quite rapid, feeble, and irregular. The type of the fever is similar to that of the primary form.

Blood.—There is usually marked leukocytosis of the polynuclear type. Absence of leukocytic increase is of serious meaning, implying lack of resistance. On the other hand, a high leukocyte count does not necessarily indicate a favorable prognosis, but a good reaction.

Physical Signs.—At the beginning of the attack the only sign is the presence of subcrepitant and sibilant râles, pointing to general bronchitis. Shortly larger or smaller areas of consolidation become manifest. At first rapid breathing, and soon cyanosis, affecting first the lips and conjunctivæ, may be observed; later, the face becomes dusky and the finger-tips blue. *Palpation* shows defective expansion and increased tactile fremitus over the consolidated areas. The *percussion-note* is dull or, less frequently, hyperresonant if the area be small. *Auscultation* reveals numerous fine, subcrepitant râles, corresponding to the consolidated portions. The respiratory murmur may be bronchial, though more often broncho-vesicular. The signs are usually noted in both lungs. Confluence of the numerous, small, consolidated areas may result in large fields of dulness, and true bronchial breathing. In cases of extensive consolidation, there may be inspiratory retraction of the lower sternum and lower ribs, indicative of deficient lung expansion (Butler).

Duration.—(1) In children this varies in different cases. Rarely do fatal instances last more than two or three weeks, while they may be as brief as two or three days. On the other hand cases in which recovery

ensues frequently last from six to eight weeks, though rarely from one to three weeks only. Two special forms demand brief description :

(a) The *cerebral*, in which restlessness, convulsions, and delirium become so marked as to overshadow entirely the pulmonary symptoms. Not infrequently the onset is characterized by convulsions, high fever, prostration, and alternating stupor and delirium. After the lapse of from two to five days, pulmonary symptoms appear, while the cerebral decline.

(b) Other cases may manifest a *subacute onset*, in which there is anorexia and occasional vomiting, with the nervous symptoms before noted.

(2) The *protracted forms* are those in which (a) the symptoms of

FIG. 46.—Illustrating broncho-pneumonia. The dark spots represent the consolidated areas; the white dots indicate mottles: A, coalescence of two areas of consolidation.

acute broncho-pneumonia give place to those of a similar though chronic state. The general disturbances may not be marked in some instances, but usually there are cough, loss of appetite, or inability to gain in flesh and strength, and the signs of consolidation persist. (b) Those presenting fever of an irregular type, together with decided prostration, in addition to the symptoms of the preceding variety. In many cases belonging to this form the lesions are tuberculous.

In adolescence the cerebral symptoms are not as well marked as in children. Two anomalous varieties are met with in practice:

● **General Broncho-pneumonia.**—The attack develops suddenly and is severe. There are chills, high fever, marked prostration, headache, chest and loin pains, a rapid pulse (soon becoming feeble), rapid and labored respirations, cyanosis, restlessness, delirium, and cough that is at first dry, and followed by muco-purulent, blood-tinged sputum.

The physical signs are defective expansion and an increased tactile fremitus. The percussion-note may be either normal, tympanitic, or dull; the auscultatory signs are large moist, subcrepitant, crepitant, sibilant, and sonorous râles over both lungs, and a harsh or broncho-vesicular respiratory murmur. The affection is very grave.

Resembling Tuberculous Broncho-pneumonia.—The symptoms appear slowly, and the case pursues an insidious course. Cough, catarrhal expectoration, moderate fever (hectic type), and night-sweats are noted.

Physical examination discloses generalized bronchitis, coupled with circumscribed areas of consolidation. Resolution may take place at the end of eight or ten weeks, and complete recovery ensue; when, however, this favorable event does not occur, the case drags on for an indefinite period, and finally ends fatally. There are no tubercle bacilli in the sputum.

Diagnosis.—This can be arrived at by considering—

(a) The nature of the antecedent affections and their etiologic circumstances;

(b) The distribution of the consolidated areas in both lungs;

(c) The fact that the physical signs of consolidation are subsidiary to those of generalized bronchitis;

(d) The intense dyspnea and cyanosis;

(e) The type of the fever, irregular as a rule, and its gradual decline;

(f) The frequent long duration.

Differential Diagnosis.—Doubtless, *lobar pneumonia* is constantly mistaken for broncho-pneumonia, and particularly when, in the latter disease, a large portion of one or both lungs becomes inflamed in consequence of the coalescence of small foci of consolidation. The points of distinction may be tabulated as follows:

BRONCHO-PNEUMONIA.

LOBAR PNEUMONIA.

Etiology.

Presence of pathogenic organisms¹ (streptococci).

Presence of the *Diplococcus pneumoniae*.

Usually secondary to bronchitis and acute infectious diseases (*e. g.* measles, whooping-cough).

Usually a primary disease.

Clinical History.

Onset gradual, without vigor.

Onset abrupt, with vigor; previous health generally good.

Fever is, in proportion to the extent of inflammation, of irregular type, and declines by lysis after a variable duration.

Fever is high, of continued type, and falls between the fifth and ninth days by crisis.

¹The diagnostic value of the discovery of streptococci is not pronounced. Numerous other organisms have been found in broncho-pneumonia, and a similar organism (*Streptococcus pneumoniae*, Weichselbaum) in cases of croupous pneumonia.

| | |
|---|---|
| Sputum glairy, tenacious, and in adults may be blood-tinged. | Sputum characteristic (rusty, or prune-juice). |
| Dyspnea and evidence of carbon-dioxide poisoning prominent. | Dyspnea and cyanosis relatively less marked; anxious countenance. |
| Herpes labialis absent. | Herpes labialis commonly present. |
| Physical signs of generalized bronchitis always marked, and usually preponderating over those of consolidation. | Signs of bronchitis generally absent, those of lobar consolidation always preponderating. |
| Consolidation commonly bilateral. | Commonly unilateral. |
| Duration indefinite, often extending over many weeks. | Duration definite as a rule, convalescence following crisis. |
| Consolidated areas liable to become the seat of tuberculous infection. | Far less likely to become the seat of tuberculous infection. |

It may be difficult to distinguish *tuberculous broncho-pneumonia* from the disease under consideration. Indeed, a non-tuberculous broncho-pneumonia may be located at the apex of the lung. The differentiation is to be based upon the presence or absence of the signs of softening, and upon a microscopic examination of the sputum (which in a child may be vomited), and the tuberculin test. The softening in tuberculous pneumonia does not, however, begin very promptly; but if elastic fibers and tubercle bacilli be found, the diagnosis is at once set at rest. Hemoptysis confirms the diagnosis of the tuberculous form.

Prognosis.—In broncho-pneumonia the severity and gravity of the symptoms and the extent of the involvement of lung-tissue are proportionate to one another; hence it follows that the disease may either be devoid of serious import or fraught with great danger to life. Its course is subject to decided fluctuations, the periods of exacerbation in the symptoms often marking the time of the development of the gravest features. Apart from the extent of the lung-tissue involved, however, we must consider especially the condition of the patient at the time of invasion. If the constitution have been previously undermined, broncho-pneumonia is very apt to be fatal. The disease is less dangerous when it develops in the course of, or follows, measles than when secondary to whooping-cough, influenza, or diphtheria. Wiry, thin children seem to stand broncho-pneumonia better than fat, flabby ones (Osler). During childhood, the younger the subject, the higher the death rate (Hare). *Deglutition* and *inspiration* lobular pneumonia, especially when occurring after operations upon the larynx or trachea, are frequently fatal. The mortality rate in this disease varies from 25 to 50 per cent. In primary broncho-pneumonia, however, the mortality is decidedly lower.

Treatment.—**Prophylaxis.**—There are few diseases that can be so effectually prevented as can broncho-pneumonia. In the first place, proper attention to the mouth as well as to the position of the patient (which should be changed frequently) during attacks of acute infectious diseases will prevent its development in a great proportion of this large class of cases. Adequate protection against exposure to cold during convalescence from measles, whooping-cough, etc. is also a potent factor in preventing the disease, as is the timely handling of catarrhal affections of the nose, pharynx, larynx, and larger bronchi.

Treatment of the Attack.—Certain *sanitary arrangements* are of the utmost practical importance. The sick-room should be well ventilated and its atmosphere kept at a uniform temperature—68° to 70° F. (20°–21.1° C.). The air of the room should also be well laden with moisture, which may be generated from a croup-kettle or other suitable vessel.

Local Measures.—In young children the chest should be enveloped in a jacket-poultice of linseed meal, which should be covered with a layer of oiled silk or waxed paper to prevent its growing cool. This should be renewed at intervals of about six hours. After the more active symptoms have subsided the linseed jacket-poultice may be replaced by one of absorbent cotton, which should also be covered with oiled silk or wax paper. In older subjects the application of iced poultices to the chest exercises a most favorable influence, not only upon the local inflammation, but also upon the fever and the nervous symptoms.

General Measures.—High fever calls for tub-baths, the temperature of the water at first being set at 95° F. (35° C.), and then gradually cooled to 75° or 80° F. (26.6° C.). The gradually cooled bath or the cold pack may be used two or three times daily. The effects are to reduce temperature, to promote refreshing sleep, and to improve the character of the respiration. This mode of treatment is especially effective in cases that begin abruptly. In such the tincture of aconite or veratrum viride may be employed temporarily. In cases presenting moderate pyrexia cold spongings, combined with the use of the ice-bag to the head, may suffice. The following fever-mixture may be employed, though it is not to be regarded as a substitute for hydrotherapy, but is merely supplemental to the latter:

R̄. Potassii citrat., zĩjss (10.0);
 Spts. ammon. aromat., fĩj (8.0);
 Spts. æther. nitrosi, fĩss (16.0);
 Liq. ammon. acetat., fĩĩj (96.0);
 Glycerini, q. s. ad fĩiv (128.0).—M.

Sig. zĩ (4.0) every two hours for a child of five years.

In *children* a mild mercurial purge at the outset is advantageous, and subsequently by the use of salines or glycerin suppositories a daily evacuation of the bowels is to be secured.

The Diet.—The bodily strength is to be maintained by careful, methodical feeding, milk, eggs, albumin, and broths being the best forms of food. The milk should be predigested if there be marked pyrexia, and egg-white may be given in cold water or as egg-lemonade. The cough is often wellnigh constant and very distressing. Frequently the use of remedies that promote secretion, combined with a small dose of opium, will, under these circumstances, afford relief. A useful formula is the following:

R̄. Vini antimonii, zĩ (4.0);
 Spts. æth. nit., zĩjss (10.0);
 Tr. opii camph., zĩjss (10.0);
 Liq. ammon. acetat., q. s. ad zĩj (64.0).—M.

Sig. zĩ (4.0) every two hours, diluted, for a child of from three to five years.

Dover's powder is also of value in relieving the cough. When the expulsion of the sputum is attended with great difficulty the preparations of ammonium often meet the indications. Of these the muriate is the most effective, but, unfortunately, this is often objected to, and we must

then rely upon the carbonate or the aromatic spirits. The bronchi may contain an abundance of secretion that cannot be expelled, despite the use of the above measures. Under these circumstances an emetic may be given, composed of the wine of ipecac (3j—4.0), combined with alum (gr. xx to xxx—1.296—1.944), and administered to a child every ten or fifteen minutes until emesis occurs. Oxygen by inhalation is to be used early and persistently to overcome the cyanosis.

Cardiac stimulants (alcohol, strychnin, Hoffman's anodyne) are required if the pulse fails, with increasing cyanosis. The preparations of ammonium owe much of their reputation in this disease to their stimulating properties. These agents when boldly used may suffice to re-establish the cardio-pulmonary circulation. Sudden heart exhaustion may occur, associated with mucous râles in the larger bronchi and rapidly developing cyanosis; atropin (dose, gr. $\frac{1}{500}$ to $\frac{1}{200}$ —0.0001—0.0012 gm. every second or third hour) tends to arrest this mucous secretion. Alternating douching with hot and cold water and electricity should be given a trial. Injections of salt solution increase arterial tension and act as a "whip" to all emunctories, aiding in the elimination of toxins. They should be used in serious cases. In streptococcic broncho-pneumonia antistreptococcus serum may be tried.

PULMONARY ATELECTASIS.

(*Collapse of the Lungs ; Compression of the Lungs.*)

Definition.—Atelectasis of the lungs is a condition occasioned by the removal of the air from the air-cells—a state directly the opposite of emphysema. The air disappears largely in consequence of the process of absorption.

Pathology.—The affected lung-spots sink in water, being non-crepitant. They present through the pleura a bluish-red tint, and on cross-section a brownish-red color. The surface of the affected areas is smooth and depressed. The bronchi supplying the collapsed parts may be occluded by inflammatory products, but, as shown by Legendre and Bailly, the air-cells involved may be inflated by means of a blowpipe.

Apart from more or less capillary distention, there are no *histologic* changes in the atelectatic areas, though they are of firm consistence (splenization, carnification). There can be no longer any doubt as to the entire propriety of the pathologic distinction between lobular pneumonia and atelectasis.

Etiology.—The condition occurs most frequently in the new-born, and is then due to defective respiration. Thus in children dying soon after birth the lower lobes may be found to be atelectatic. When acquired, however, there are three modes of production: (1) The first step consists in a more or less complete plugging of the smaller bronchi with muco-pus and other products of bronchial inflammation. If complete, air can no longer enter on inspiration, and as the contained air gradually becomes absorbed atelectasis is the natural result. This condition is very commonly associated with broncho-pneumonia, especially in children. New growths may occlude the smaller bronchi and produce a

similar result. (2) A frequent mode of origin is through compression of the lungs, resulting from positive intrathoracic pressure, after the normal contractility of the lung has been overcome. Instances of this may be produced by pleural effusion, hydrothorax, pneumothorax, pericardial effusion, great cardiac hypertrophy, a solid tumor, or an aneurysm of the arch. Not infrequently abdominal tumors, excessive meteorism, and ascites make sufficient upward pressure against the diaphragm to cause compression of the lower lobes of the lungs. (3) Conditions that weaken and obstruct the inspiration may produce this disease, such as certain brain-affections, paralysis of the pneumogastric, and paralysis of the chest-walls. Thoracic deformities may produce pulmonary atelectasis, and in extreme grades of kyphoscoliosis the lung occupying the side corresponding to the convexity of the spinal column is small. Whilst the lung-expansion and the growth of the organ are greatly interfered with, true atelectasis rarely occurs from this cause, particularly if the condition arises in youth, owing to the natural retractility of the lung. Among conditions arising from deformities of the chest is the so-called aplasia of the lungs.

Symptoms.—Atelectasis is a secondary condition, and its symptoms are very generally veiled by those of the primary disease. It arises frequently in the course of broncho-pneumonia, but passes unnoticed unless it becomes very extensive. *Respiration* is carried on by the upper and anterior portions of the lungs, is increased in frequency, and is laborious. The *pulse* is small, rapid, and feeble; the *skin-surface*, especially that of the extremities, is cool.

The form presenting the most typical symptoms is that occurring in the new-born. It is evidenced by *shallow, rapid breathing, lividity, cold extremities, a faint whining cry, drowsiness*, and sometimes by evidences of *motor irritation*, such as muscular twitching and convulsions. Congenital anomalies of the circulatory organs are associated.

Physical Signs.—When it involves a goodly portion of the lower lobes posteriorly, as frequently happens, there is marked retraction during inspiration over the lower portion of the thorax, due partly to external atmospheric pressure, and partly to the contractile efforts of the diaphragm. Dulness on percussion is only revealed when the atelectasis is extensive, and the tactile fremitus, though very various, is generally decreased or even absent. Localized compensatory emphysema may present semitympanitic resonance over small areas of collapse.

Auscultation shows a greatly diminished or absent vesicular murmur, and, if the area of collapse be large, bronchial breathing. Among associated sounds is the subcrepitant râle, due to broncho-pneumonia, and, indeed, capillary bronchitis and atelectasis are often combined, there being, moreover, no reliable signs that will separate them clinically.

The *aplasia* of the lung that is produced by spinal curvature (*kyphoscoliosis*) richly deserves brief separate description, owing to its clinical importance. In many instances the chest is more or less twisted on its own axis, shortened in the vertical diameter, and thoroughly fixed. Under these circumstances lung-expansion is impossible, and hence respiration is purely diaphragmatic. In many other patients life may be prolonged for an indefinite period, nothing more being observed than

slightly labored breathing. Such persons, however, upon great physical exertion suffer from urgent dyspnea, and the development of an ordinary bronchitis may lead to similar results, and even to speedy death.

The **physical signs** are those of localized emphysema, combined with those of more or less compression of the lungs. There is an extension of the cardiac dulness to the right, and other evidence of right ventricular enlargement, to which may succeed dilatation with its usual clinical events. Death is not rarely due to this failure of compensation.

Autopsies have shown the lungs to be small and more or less compressed, some portions being almost airless. Areas of emphysema are often associated. The right ventricle may be hypertrophied merely, or dilatation may also have taken place. Congenital atelectasis, by keeping up high pulmonary pressure, may lead to persistence of the ductus Botalli and of the foramen ovale.

Diagnosis.—Atelectasis may be distinguished from *lobar pneumonia* by the absence of an initial rigor, fever, crepitant râles, and the pain of the latter disease, and by the characteristic inspiratory retraction of the lower portions of the chest and the smaller areas of dulness.

Pleuritic effusion gives a flat percussion-note, the upper level of which varies with a change in the position of the patient—a sign that is wanting in atelectasis.

Prognosis.—When the condition is limited to small areas it is rarely serious, but equally seldom does extensive atelectasis lead to recovery. The outlook depends to some extent upon the nature of the associated affections; thus, when secondary to whooping-cough and widespread broncho-pneumonia, it is very fatal. Other diseases that may complicate and increase the gravity of the atelectasis are pleurisy and pulmonary tuberculosis. On the other hand, compensating emphysema often coexists, and is to be regarded as salutary in its effects. When due to *compression* by pyo-pneumothorax, tumors, and the like, the prognosis is especially gloomy.

Treatment.—The treatment corresponds with that of the primary disease. *Capillary bronchitis*, which is so apt to be followed by collapse of the lobules, must receive active treatment, and prophylactic measures are of the utmost practical importance. The patient should be instructed to practise full inspiration at regular intervals; he should not be allowed to lie continuously in the dorsal decubitus, but should change his position frequently. Another useful preventive measure is the use of cold shower-baths (*i. e.*, a stream of cold water poured over the region of the neck), and this can sometimes be depended upon as a curative agency when the condition already exists. Tonics and the judicious use of stimulants, together with a nourishing diet, are invariably required. I have also seen good results follow the inhalation of compressed air and of oxygen.

In *kyphoscoliosis* tepid baths are indicated. The heart-condition demands careful attention, and cardiac stimulants are to be resorted to at the first loss of compensation or when compensation fails to become established.

EMPHYSEMA.

Definition.—In general this term implies the presence of air in the interstitial alveolar tissue. As applied to the lungs, however, two forms are recognized: (1) Interlobular; and (2) Vesicular, an abnormal dilatation of the alveoli.

INTERLOBULAR EMPHYSEMA.

This is produced by the rupture of the air-cells, the air contained in the lung escaping into the interlobular connective tissue. Among its causes are—(a) Injuries of the lung (usually by a fractured rib) and penetrating wounds of the chest; (b) Violent paroxysms of coughing, as in whooping-cough; and rarely defecation, parturition, and hysterical convulsions. When arising in this way its favorite situation is the anterior margin of the upper lobe.

Pathology.—In the interlobular septa immediately beneath the pleura air-bubbles are sometimes seen to be arranged in well-defined rows. The pulmonary pleura may become detached, and the air-tumors may then become as large as an English walnut or even of greater size. Unlike the condition in vesicular emphysema, these sacs are freely movable, and the air may find its way from the root of the lung into the mediastinal connective tissue, and thence into the subcutaneous tissue of the neck and the wall of the thorax. Rarely these air-sacs perforate the pleura, setting up pneumothorax, with or without pleuritis.

Interlobular emphysema is sometimes associated with advanced vesicular emphysema.

VESICULAR EMPHYSEMA.

(*Alveolar Ectasis.*)

Definition.—Dilatation or enlargement of the alveoli and infundibular passages.

Varieties.—The cases are classified into—(1) Compensating, (2) Hypertrophic, and (3) Atrophic forms.

COMPENSATING EMPHYSEMA.

This variety is limited to certain parts of the lung, and arises in consequence of pathologic changes in other parts of the same organ that prevent full expansion of the lung on inspiration. Hence a vicarious increase in the volume of the air-cells is observed in circumscribed morbid processes such as occur in pulmonary tuberculosis, lobular pneumonia, cirrhosis, and pleurisy with adhesions (particularly when the latter is situated at the inferior border of the lung). An entire lung, unaffected by the primary disease, may be the seat of compensating emphysema when the causal disease invades the whole or a greater portion of the other lung, as in cirrhosis, extensive pleurisy with effusion, lobar pneumonia, and pyo-pneumothorax. When, however, the latter conditions are confined to a portion of one lung, the remainder of the same organ becomes distended also. The term *acute emphysema* is applicable to many of the cases.

As a rule, this pulmonary change is physiologic and beneficial: only rarely secondary atrophy of the walls of the air-cells develops.

Symptoms are not presented by the lungs in consequence of the changes met with in compensating emphysema. The condition is sometimes recognizable by means of the usual physical signs, but even these are not always to be relied upon. Fortunately, its existence may be safely inferred when there is conclusive evidence of the presence of the local causative diseases (broncho-pneumonia, pulmonary tuberculosis, pleurisy, lobar pneumonia).

HYPERTROPHIC EMPHYSEMA.

Nature of Emphysema.—The symptoms are dependent upon a loss of elasticity in the lungs, and, the latter condition being the result of overstretching, the contractile energy of the lungs is in great part destroyed; hence they become permanently enlarged. We may in some cases account for the loss of elasticity in the lungs by the operation of causes that produce an abnormal degree of stretching, either temporarily or constantly; but under these circumstances emphysema would be developed despite the pre-existence of normal contractility of the lung. In true emphysema, however, which develops at a comparatively early period in life, we may safely assume that the retractile energy is defective (probably a congenital condition), and hence in such cases the action of the usual causal factors will speedily engender over-distention, or emphysema may develop even in the absence of causative influences. In these instances there is probably a quantitative as well as a qualitative defect in the elastic-tissue element of the lungs.

Pathology.—The thorax is enlarged (barrel-shaped), and upon removing the sternum the lungs are found completely to fill the mediastinum, and do not retract as in health. They present a pale, anemic appearance, although pigmented patches and streaks may be noted. To the touch they appear soft and feathery, though dry. They readily pit on pressure (a leading characteristic).

Immediately beneath the pleura enlarged air-cells can be distinguished macroscopically, and air-sacs as large as a walnut may project above the lung surface. Occasionally they may be pedunculated. At the anterior borders a series of air-blebs, resembling a frog's lung, may be observed. Here, and near the root of the lung, distention is usually more marked, owing to the direction taken by the distending force. The pleura is pale, and in patches the pigment may be absent (*Virchow's albinism*).

Upon microscopic examination it is observed that the dilatation starts in the infundibular and alveolar passages. The septa are partially obliterated, the alveolar walls thinned and, lastly, perforated, while in consequence of these changes the air-cells communicate with one another, forming larger or smaller air-sacs. The process is an atrophic one, the smaller elastic fibers disappearing, while the larger become less prominent and often ruptured. After the latter changes have begun the capillaries likewise disappear, and the epithelium of the air-cells undergoes fatty degeneration, though in the larger bullæ a pavement-layer is retained. The smooth muscular element may also occasionally be found hypertrophied

(Rindfleisch). The clinical phenomena probably arise from the loss of the capillary blood-vessel system and collateral hyperemia of the larger bronchial vessels.

The bronchial mucous membrane is usually the seat of chronic inflammation. It may be roughened and thickened, or the submucous elastic tissue may present prominent longitudinal lines, while the bronchial mucosa is covered with muco-pus. The smaller tubes may be dilated (*bronchiectasis*), and hyperplasia of the peribronchial connective tissue may be associated. The diaphragm is lowered and the subjacent viscera correspondingly depressed.

Physiologic Pathology.—The heart is pushed downward and somewhat backward. The right side shows well-marked changes; the cavities are dilated and hypertrophied, due to obstruction in the pulmonary circulation; and in long-standing cases hypertrophy of the left chambers may also develop. The pulmonary artery and its branches are enlarged and the seat of atheromatous degeneration. The liver, kidneys, and other viscera present the changes that belong to chronic venous engorgement.

Etiology.—The affection is often secondary to, and develops in consequence of, other affections of the lung—notably *whooping-cough* and *chronic bronchitis*, particularly the dry form. The disease is attributable to the mechanical influences to which the alveolar walls are subjected during respiration. This abnormal strain attends inspiration to some extent, but mainly expiration, owing to the obstruction to the egress of the air in the smaller bronchi, with increased *intra-alveolar air-pressure*. The increased tension in the air-cells may be accounted for partly by the severe and persistent cough, the air being thus driven into the apices of the lungs, forcibly expanding them and causing emphysema. Syphilis and alcoholism are among the recognized causes.

Bronchial asthma, on account of the obstruction of the exit of the air from the lungs, produces during the attacks an acute emphysema that may result finally in a condition of permanent overdistention. *Certain occupations*, such as blowing wind-instruments, or those that entail severe muscular strain (*e. g.* blacksmithing), act as predisposing causes, and hence, emphysema is of common occurrence among the working classes, and is more common in males than females. Edsall's studies, however, show that glass-blowers and players on wind instruments are not especially liable. The constant straining in certain pelvic disorders may induce emphysema. The disease is often *hereditary*. During *advanced years* the lung-elasticity often diminishes, and as a consequence a disposition to emphysema is engendered. On the other hand, emphysema is not infrequently met with in children, and in such there may be a temporary respite, with a recurrence at a later period. An emphysematous tendency also results from congestion of the lungs associated with mitral valvular disease.

Clinical History.—In nearly all cases the disease develops insidiously, the symptoms being gradually added to those of the primary affections (chronic bronchitis, asthma, etc.). When due to occupation its development is also slow, and not infrequently its origin dates back to childhood or beyond the recollection of the patient. Rarely it may exhibit a more acute development, *e. g.*, after whooping-cough.

The first symptom is a variable degree of *dyspnea*, and to this may

be added temporary *cyanosis* and *cough*. The severity of the dyspnea varies with the degree of distention of the air-cells, even though additionally aggravated by the coexistence of the primary disease. In moderate emphysema the dyspnea is only apparent on going up stairs, running, walking rapidly, or after a hearty meal; on the other hand, in advanced grades of the affection it is constant, and is intensified by the slightest exertion, even to orthopnea. Speech is interfered with, the patient's utterances taking the form of fragmentary sentences or syllables. The labored breathing is shown particularly in expiration, and, as in asthma, in which the alveolar spaces are acutely distended, so in emphysema the rhythm of the respiration is changed. The inspiration is shortened, and the expiration is greatly prolonged and accompanied by wheezing when chronic bronchitis coexists.

In the later stages cyanosis becomes more marked, and is noticeable in proportion to the loss of compensation and interference with the cardio-pulmonary circulation. It often attains to an extreme degree, and the patient's alarming appearance may be in striking contrast with his apparent degree of comfort. In mild forms the cyanotic tint is confined to the lips, lobes of the ears, and the extremities. Any increase in the degree of dyspnea after exertion results in an increased blueness of the surface.

The *cough* is dependent upon the presence of chronic bronchitis, which frequently co-exists, particularly during the winter. The expectoration is identical with that of chronic bronchitis, and when this disease reaches an advanced stage the cough persists throughout the year (*vide* Chronic Bronchitis). Intercurrent acute attacks of bronchitis are often followed by temporary attacks of asthma; and since chronic bronchitis in its highest grades is met with at an advanced period of life, so, as would be expected, the cases of advanced emphysema are also met with at the same period. Osler has described a group of cases occurring in patients "from twenty-five to forty years of age who, winter after winter, have had attacks of intense cyanosis in consequence of an aggravated bronchial catarrh." These patients are short-breathed from infancy, and their condition is attributed to a primary defect of structure in the lung-tissue.

General Symptoms.—There is no fever, the temperature being generally subnormal, and the pulse, though sometimes feeble, is not increased in frequency. There is a very gradual loss of flesh and strength, and the patient is stoop-shouldered, presenting a peculiar cachectic appearance—in strong contrast with the dusky appearance of the face, the swollen neck, and the enlarged chest.

Finally, other symptoms may be mentioned that are for the most part secondary to hypertrophy, followed by dilatation, of the right ventricle. This hypertrophy is the result of pulmonary congestion and obliteration of the pulmonary capillaries induced by the emphysema. Under these circumstances severe attacks of cough occur, attended with extreme dyspnea and lividity, and later the conditions that usually succeed a moderate grade of tricuspid insufficiency supervene, such as congestion of various viscera and edema of the feet. Anasarca is rare.

Physical Signs.—The shape of the chest is characteristic: owing

to the increased antero-posterior diameter, it becomes barrel-shaped (Fig. 47), and the sternum bulges, as do also the costal cartilages.

FIG. 47.—Barrel-shaped chest in emphysema.

The infraclavicular and mammary regions are also prominent, and give the thorax an abnormally rounded appearance. The episternal notch is deeper than the normal, the clavicles and muscles of the neck are unduly prominent, and the neck itself appears to be shortened, owing to the elevated position of the clavicles and the sternum. There is an antero-posterior curvature of the spine and a winged condition of the scapulæ. Below, the thorax appears contracted. The intercostal spaces are widened and depressed, and a network of dilated venules frequently extends laterally above the inferior costal border.

The movements of the chest are vertical rather than expansile, and the lungs are constantly in a state of extreme expansion; in the

lower thoracic and upper abdominal regions there may be observed retraction rather than expansion during the act of inspiration. The respiratory acts, as a whole, are labored, and the diaphragm and abdominal muscles are seen working with considerable violence. The heart's apex-beat is invisible, but marked epigastric pulsation is frequently noticeable. Venous pulsation may be seen in the neck after failure of the right ventricle has occurred.

On *palpation* the character and direction of the chest-movements may be accurately appreciated. The tactile fremitus is decreased, but not absent. In the early stages the apex-beat is feeble, while in advanced cases it cannot be felt. Owing to displacement of the heart and engorgement of the right ventricle there is a distinct systolic shock over the ensiform cartilage, and also a pulsation in the epigastrium.

Percussion yields a characteristic hyper-resonance. This may be distinctly "Skodaic" or semi-tympanitic, and in extreme instances the tone may be woodeny. The area of percussion-hyper-resonance extends higher above the clavicles than naturally. The area of cardiac dullness is lessened and finally obliterated by the distended lungs; while the upper limit of liver-dullness, both anteriorly and posteriorly, is found to be one or two interspaces lower than normal, owing to the fact that the diaphragm is depressed. The upper level of splenic dullness is also lowered.

On *auscultation* the inspiration is short and feeble, while the expiration is greatly lengthened, the normal ratio of these sounds being reversed. Their pitch is somewhat lowered, particularly that of expiration; and

when râles are present the respiratory murmur (particularly the inspiratory) may be scarcely audible. In well-marked instances of emphysema inspiration and expiration may rarely be of equal length. It is a fact worthy of emphasis that the parts of the lungs less markedly emphysematous than others give a harsh, exaggerated vesicular murmur, owing to the great efforts of breathing. Râles of various sorts are frequently audible, due to the accompanying bronchitis usually present; less frequently the auscultatory signs of asthma, pleuritis, and phthisis are encountered. Rarely, rubbing sounds, attributed to the friction of enlarged air-cells against the pleura, are audible, and when the interlobular variety supervenes upon vesicular emphysema a *crumpling* sound is heard. The so-called "*Laennec's râle*," which resembles somewhat the subcrepitant râle, is not infrequently present. The vocal resonance varies from an almost total absence to a greatly increased intensity. The tricuspid insufficiency that develops late in this affection is betrayed by its characteristic murmur.

Diagnosis.—A positive diagnosis may be arrived at from a consideration of the history, including such points as heredity, occupation, the long duration of the condition, coupled with the most characteristic symptoms (dyspnea, cyanosis, signs of chronic bronchitis), and from the physical signs. In a case of beginning emphysema, particularly among children, a certain diagnosis is not to be attempted.

Differential Diagnosis.—*Pneumothorax* is the disease most apt to be confounded with emphysema. It develops suddenly, however, while emphysema is of slow development, and the rational symptoms of pneumothorax are more constant and urgently distressing than those of emphysema. *Pneumo-thorax* is unilateral, and gives a purely tympanitic percussion-note, while hypertrophic emphysema is bilateral and its percussion-note is hyper-resonant. Amphoric breathing, metallic tinkling, the characteristic succussion splash, and an absence of the vesicular murmur, usually present in pneumo-thorax, are absent in emphysema.

Another affection giving rise to dyspnea, cough, and cyanosis is *pleurisy with effusion*, but the slow course, the absence of fever, and the universal hyper-resonance that characterize emphysema do not belong to pleurisy. The latter affection yields a flat percussion-note.

Prognosis.—Hypertrophic emphysema of acute form (*e. g.*, resulting from whooping-cough) is often curable; but the usual slowly generated variety gives an unfavorable prognosis as to recovery. In many cases, however, life is not materially shortened. Temporary improvement is possible when the lesion consists merely of a distention of the air-cells, and is shown by a corresponding improvement in the physical signs. If the vital capacity, as shown by the spirometer, is reduced one-half or more, the prospect is unfavorable. Recurring attacks of bronchitis intensify the symptoms of a disease that is innately progressive. Intercurrent affections, such as pneumonia (lobar and lobular) and pulmonary tuberculosis, may prove fatal. Dropsy, following broken compensation, is a dangerous complication; other late accidents are hemoptysis and sudden dilatation of the right heart.

Individual circumstances, such as the patient's social condition, the stage of the affection in which he comes under proper treatment, and the degree of care he is willing to exercise, greatly influence the outcome of the case.

Treatment.—The treatment is to be directed toward the removal of the causes of emphysema, and chiefly of the chronic bronchitis. From personal observation I am firmly convinced that the progress of the disease can be arrested, and that the condition is sometimes improved, by relieving the chronic bronchitis. The iodids (potassium, sodium, and ammonium) at times produce effects that are truly remarkable. If not well borne by the stomach, the syrup of hydriodic acid may be employed. If the occupation of the patient tends to aggravate the disease, it must be forsaken for a less harmful one. Violent paroxysms of cough and intercurrent attacks of asthma contribute to the production of alveolar distention, and hence must be alleviated promptly by appropriate therapeutic measures. Attacks of acute bronchitis are to be prevented, if possible, by suitable clothing, by avoidance of exposure to inclement weather, dust, and the vitiated atmosphere of overcrowded halls, churches, and the like; whenever practicable the result can be most successfully obtained by a residence in an equable climate. Since a severe bronchitis is apt to increase the severity of the emphysematous symptoms, it must be relieved as speedily as possible.

Passive congestion, flatulence, and constipation, with other gastrointestinal symptoms, demand careful regulation of the diet and especially a restriction in the use of carbohydrates. The bowels must also be moved regularly with the same end in view.

The heart needs to be carefully watched, and as soon as signs of broken compensation appear digitalis and strychnin will be found highly useful. Diuretics and cathartics may also become necessary. The sudden development of urgent dyspnea and extreme lividity, especially if associated with weak cardiac action and a rapid, feeble, irregular pulse, calls for free bleedings. In my hospital practice I have seen the lives of patients suffering from emphysema saved by timely venesection.

To assist the patient in expiration Gerhardt has suggested systematic *mechanical compression* of the thorax during expiration as a useful measure. Pressure is made by an attendant, who places his hands flat on the lower lateral portions of the thorax, and the manipulation is to be continued for from ten to fifteen minutes daily. The results obtained by certain German authors have been encouraging, but in my own hands the method has failed, except in two instances occurring in young adults with yielding chest-walls, in whom it was of the greatest service. The *pneumatic treatment*, comprising the inhalation of compressed air and the breathing into rarefied air, richly deserves further trial,¹ its use having been productive of permanent improvement in a number of cases, as shown by physical examination (including mensuration). Oxygen by inhalation has proved serviceable.

SENILE EMPHYSEMA.

This variety is in reality a senile atrophy of the lungs, and has been appropriately termed "small-lunged emphysema" by Sir Wm. Jenner. In consequence of the complete atrophy of the alveolar walls, coalition of the air-cells takes place, with the production of large air-sacs. The

¹ Waldenberg's portable apparatus is not convenient for use.

lungs contain less than the normal volume of air, instead of an abnormal quantity as in true hypertrophic emphysema, and as a result occupy less space in the chest-cavity than do healthy lungs. The pulmonary tissue elements are deeply pigmented. The condition does not produce right ventricular hypertrophy.

The **symptoms** are negative, although subjects in whom senile emphysema develops may have previously had chronic bronchitis with more or less dyspnea. They quite frequently present a withered appearance, and the chest on inspection is seen to be contracted, owing to the fact that the ribs approximate more closely and take a more oblique direction than in health.

Treatment is unavailing.

GANGRENE OF THE LUNGS.

Pathology.—The affection presents itself in two forms—as a (*a*) diffuse, and a (*b*) circumscribed process.

(*a*) The **diffuse** variety is rare. It may, however, be met with in lobar pneumonia, and very rarely in consequence of occlusion of the large branch of the pulmonary artery; it may also be secondary to the circumscribed form. The greater part of the lobe, or even an entire lung, may be involved, the pulmonary parenchyma degenerating into a putrid, greenish-black, pulpy mass, with no obvious line of demarcation.

(*b*) The **circumscribed** form may involve either one or both lungs, though the right is affected somewhat oftener than the left. To this category belongs the so-called *embolic gangrene*, the nodules of which have their favorite seat in close proximity to the pulmonary pleura. All etiologic varieties of the circumscribed form more frequently implicate the lower than the upper lobe of the lung, occurring in sharply defined areas, which may either be single or multiple. The affected area first presents a greenish-brown appearance; its central portion soon undergoes softening, and a cavity is thus formed whose walls are ragged and irregular and contain a foul-smelling, dark, greenish liquid. The surrounding lung is inflamed, and the air-sacs contain inflammatory products (fibrin, epithelium, pus), while the highly-irritating and putrid material sets up an intense bronchitis. These gangrenous foci may increase in size by a peripheral extension, and thus the adjacent veins may become plugged with infectious thrombi or the vessels may become eroded. Emboli may then be detached from the infectious thrombi, and, entering the circulation, may set up foci of septic inflammation in remote organs. A truly remarkable connection exists between circumscribed gangrene of the lung and cerebral abscess. When the gangrenous spot is situated near the pleura, simple or gangrenous pleurisy may arise as a complication, or the pulmonary pleura may be perforated and pyo-pneumothorax result. When recovery ensues the cavities formed as the result of the conversion of lung-tissue present a limiting wall of dense connective tissue. Such cavities may remain permanently or may slowly become contracted.

Etiology.—Gangrene of the lungs is caused by the bacteria of putrefaction (probably the staphylococcus albus or aureus). The disease is

rare. It is only when the lung-tissue has become impaired or peculiarly altered that the specific bacteria are capable of producing gangrene. It may occur in several ways:

(1) Secondary to lobar pneumonia, hemorrhagic infarctions, cavities in the lungs, bronchiectasis, wounds of the lung, contusions of the thorax, carcinoma of the esophagus, or to compression or embolism of the pulmonary artery or of the bronchial vessels.

(2) By lodgement of an embolus, derived from a gangrenous area in distinct parts; this form is common, especially in children. The embolus is often the result of otitis media, mastoiditis or thrombosis of the lateral sinus (Guillemot).

(3) Pressure from a thoracic aneurysm may give rise to gangrene.

(4) The most important causal factor, however, is the entrance of foreign bodies, especially bits of food, into the bronchi and lungs. Whether or not the specific bacteria of putrefaction enter the lungs with the foreign bodies, the latter render the tissue-soil receptive to the former, and once the process has been initiated it is apt to extend itself. There are several ways in which these foreign particles gain entrance into the bronchi and lungs: (*a*) By a faulty swallowing of the food; (*b*) by inhalation; (*c*) by a carcinomatous perforation of the esophagus into the bronchus or into the lung.

(5) In debilitated states of the system, as during convalescence from protracted fever (rarely), and in diabetes mellitus (frequently).

Symptoms.—These are *local* and *general*.

Local Symptoms.—There is severe *cough*, which is accompanied by an exceedingly *fetid expectoration* that is usually quite profuse. When abundant, and when expectorated into a conical glass and allowed to stand for a time, it separates into three layers: (*a*) the uppermost, being frothy, opaque, and of a grayish-yellow color; (*b*) the middle, clear and watery; and (*c*) the lowest, appearing as a greenish-brown sedimentary layer containing shreds of lung-tissue and sometimes blood. The microscope shows it to consist of numerous elastic fibers, bacteria, fat-crystals, muco-pus, granular matter, and leptothrices. Small quantities of blood in the sputum are very common. Kannenburg and Streng have also described ciliated monads as occurring in the sputum. The patient's breath is, as a rule, intensely fetid, even though there be no expectoration, but this fetor of breath may be absent, as in a case of my own (which came to autopsy), in which the localized gangrenous process had no fistulous connection with the bronchus. If any of the large branches of the pulmonary artery be eroded, free and even fatal hemoptysis will result. *Pain* in the chest is complained of when the lesions are superficially situated.

Physical Signs.—The physical signs are sometimes obscure, as when the areas involved are smaller and deeply situated, and in such instances signs of bronchitis only may be detectable. When large and favorably situated, however, the affected spots usually give signs of consolidation, rapidly followed by those of cavity. In addition bronchial râles—usually moist—and coarse cavernous râles are usually audible. It is obvious that when the pleura is implicated the signs of pleurisy are added, and if pneumothorax be present those belonging to the latter condition also.

The chief **general symptoms** are irregular fever, emaciation, and

profound prostration. Leukocytosis is found. A septic condition of the system is commonly developed, and the patient sinks from exhaustion. The serious general features may overshadow the local in the lungs. Rarely there may be an almost total absence of constitutional disturbances, and such instances terminate in recovery.

Diagnosis.—The distinctive feature is fetidity, both of the sputum and the breath. The physical signs may readily determine the existence of the pulmonary lesion, but it is difficult to eliminate *abscess* and *fetid bronchitis* associated with bronchiectasis. The results of a careful examination of the sputum, together with the less horribly fetid odor of the breath, in *abscess* will usually suffice to eliminate the latter affection. In *fetid bronchitis* the fetor of the breath and sputum is less marked, while its course is slower and more favorable than in gangrene.

Prognosis.—The prognosis is always grave, though rarely recovery in circumscribed gangrene of the lungs ensues. The chief dangers are exhaustion and hemorrhage. Improved methods of surgical treatment, however, have saved life in a few instances, and promise to reduce still further the mortality-rate of this serious affection.

Treatment.—The leading indications are—

(a) The disinfection of the gangrenous focus or foci in the lungs. This may be accomplished by the internal administration of creasote or carbolic acid or by the use of an antiseptic spray.

(b) The patient's nutrition must be maintained, if possible, by a concentrated liquid diet, administered in fixed quantities and at regular intervals; also by the judicious cultivation of the digestive functions, together with the use of stimulants and tonics. Morphine is indispensable for the cough, which would otherwise rapidly induce exhaustion. Traube suggests lead acetate when the sputum contains blood. For a description of the surgical treatment of gangrenous cavities of the lungs the reader is referred to special works on surgery. It is the physician's duty, however, to determine whether or not the patient's general condition will admit of surgical intervention, and also to localize as nearly as may be the affected zones for the surgeon's guidance.

ABSCESS OF THE LUNGS.

(*Suppurative Pneumonitis.*)

Pathology.—This affection is characterized by the formation of pus and the degeneration of lung-tissue. It may be (a) a mere infiltration of the blood-vessels, bronchi, or interstitial tissue, but more frequently is seen as (b) an ordinary abscess. In size the abscesses range from that of a walnut to an apple, and I have observed in one case inflammation of the whole of the middle lobe of the right lung. The abscess-walls are irregular and decidedly ragged; and in the case of old lesions there is a dense fibrous wall; the contents are purulent and rarely necrotic. The most common seat ("80 per cent.") is in the lower lobes. If the contour of an abscess touches the pleura, empyema is the result. Rupture of the abscess into the pleura may also occur.

Etiology.—Streptococci are found, though they are not the only direct causes of abscess of the lung. The diplococcus pneumoniae and Friedländer's bacillus have been found, as well as certain other organisms. *Predisposition* is noted in certain conditions, as (1) during or following the occurrence of inflammation, as in lobar and lobular pneumonia. Suppurative infiltration, however, more frequently arises under these circumstances than abscess, and in the rare instances in which the latter occurs it is apt to be comparatively small and multiple. In all forms of inhalation and deglutition broncho-pneumonia, however, abscess of the lung is a frequent sequela.

(2) Perforation of the lung from without or from adjacent organs, *e. g.*, esophageal carcinoma, hepatic abscess, or suppurating hydatid cyst.

(3) Infectious emboli, found in connection with septicopyemia, frequently cause metastatic abscesses in the lungs. In a mechanical manner they may produce hemorrhagic infarctions, followed by suppuration, or the latter process may occur independently of the former. The abscesses are usually situated close to the pleura, and are frequently wedge-shaped; they vary in number from one to several hundred, and in size from a pin's head to an orange.

(4) Inward extension of a purulent pleurisy.

(5) As elsewhere stated (*vide* Pulmonary Tuberculosis), suppuration is quite generally associated with chronic pulmonary tuberculosis.

Symptoms and Diagnosis.—The examination of the *sputum* is of the greatest value in the diagnosis of this disease, since, being purulent, it usually presents a yellow, or less frequently a greenish- or brownish-yellow, color. It emits a feter that is less pronounced than that of either gangrene or putrid bronchitis. Particles of lung-tissue may be visible in the pus, and on microscopic examination of the latter, elastic fibers, the presence of which is of the utmost importance in the diagnosis, may be found in profusion. The *physical signs* of cavity are of the greatest assistance in distinguishing abscess of the lung; these, however, are wanting unless the abscess is of a considerable size. The signs of cavitation, together with the characteristic sputum, leave no room for doubt. Chills and suppurative fever often attend. Leukocytosis is present. The history is of considerable importance, as confirming the more characteristic features. Thus antecedent pneumonia or septicopyemia would be strongly corroborative. *Tuberculosis* distinguishes itself by the history, the diminished amount of pus present, and the sputum test.

Prognosis.—The prognosis is often hopeless, as, for example, when the disease is associated with pyemic processes in other parts of the body. On the other hand, those rare instances in which it is secondary to pneumonia give a comparatively favorable outlook.

Treatment.—The chief aim in the therapeutics should be to support the system by the administration of tonics, stimulants, and antiseptics, as well as by energetic feeding with light forms of nourishment. Inhalation of antiseptic sprays (phenol, creosote, thymol) should be tried. When the abscess is situated near the periphery of the lung, surgical interference is to be advised as soon as the first indications of increasing weakness appear. Pulmonary abscess occurring as a sequel of pneumonia with free expectoration should receive an expectant treatment, unless it tend to become progressive, when it calls for operative intervention. For the details of the operation of pneumonotomy for pulmonary abscess

the reader is referred to works on surgery. The statistics of Eisendrath,¹ relating to abscess following pneumonia, may, however, be mentioned, as follows: of 25 cases of acute simple abscess, 24 recovered and 1 was improved; in chronic abscess the results were much less favorable.

PNEUMONOKONIOSIS.

(*Anthracosis, Chalicosis, etc.*)

Definition.—A form of chronic interstitial pneumonia that arises from the inhalation of dust-like particles. Different terms have been applied to the condition according to the nature of the dusts inhaled, the chief among these being—(1) Anthracosis (coal-miners' disease), due to the inhalation of coal-dust; (2) Chalicosis (stone-cutters' phthisis), caused by the inhalation of mineral dusts; and (3) Siderosis, caused by inhaling metallic particles, particularly iron oxid.

(1) **Anthracosis.**—Among dwellers in cities a moderate degree of pigmentation of the lung-tissue with coal-dust is the rule, while in those residing in rural districts the condition is decidedly less common. True anthracosis, however, has reference to such an accumulation of the carbon particles as can be due only to the inhalation of a well-laden atmosphere, or under other circumstances *e. g.*, when the mucous membrane is unhealthy or without perfect ciliary action. Under such conditions the normal scavengers of the respiratory organs—the mucous corpuscles lining the trachea, the bronchi, and the alveolar cells—fail to deal successfully with the numerous dust-particles that gain entrance along with the inspired air; hence some of the latter pierce the mucosa and reach the lymph-spaces and lymph-vessels. Here they are taken up by the leukocytes and are conveyed to a more remote destination. Arnold shows that after the particles enter the lymph-system they are carried “(a) to the lymph-nodules surrounding the bronchi and blood-vessels; (b) to the interlobular septa beneath the pleura, where they lodge in and between the tissue-elements; and (c) along the larger lymph-channels to the substernal, bronchial, and tracheal glands, in which the stroma-cells in the follicular cord dispose of them permanently,” with resulting indurative enlargement of these structures. Rarely the carbon particles may find their way into the general circulation; this may occur, as shown by Weigert, when the pigmented bronchial glands become adherent to the pulmonary veins. Petit² claims that anthracosis may be of intestinal origin in cases in which the mesenteric barrier has already been broken down by tuberculosis.

Anthracosis leads, primarily, to chronic bronchitis, to be soon followed by emphysema; but extensive anthracosis may be present without any other changes in the lung than the presence of carbon particles stored in the protoplasmic cells. The lung-tissue presents great variations in its degree of susceptibility to these foreign particles. Sooner or later there is usually produced, as the result of their irritant action,³ a

¹ *Phila. Med. Jour.*, Nov. 9, 1901.

² *La Presse Médicale*.

³ Cohnheim contends that coal particles do not produce irritative changes in the lung, and that the latter are due to irritating substances inhaled with the particles of coal.

proliferation of the connective-tissue elements—*i. e.*, a chronic interstitial inflammation. This fibroid change usually starts in the peribronchial lymph-structures, though the bronchial and tracheal glands are, as a rule, similarly involved at a comparatively early period. The affected lung-tissue is frequently coal-black, dense, and airless. The pneumononiotic areas vary greatly in size and numbers, and not infrequently coalesce, in which case large portions of the lung-tissue may become the seat of fibroid change. The alveolar walls are much thickened in some instances, and firm pleuritic adhesions exist. Bronchiectatic cavities may be present, and later necrotic softening of the indurated areas occurs, leading to the formation of small cavities that contain a dark fluid. When the latter communicate with the bronchi their walls are prone to ulcerate. I have noticed that the process almost invariably terminates in pulmonary tuberculosis, and particularly is this true of cases that follow the inhalation of mineral and vegetable dusts (*vide infra*).

(2) **Chalicosis.**—Changes similar to those previously described are induced in the pulmonary connective tissue by the inhalation of stone-dust by those who follow such occupations as stone-cutting, knife- and axe-grinding, and millstone-making. The irritating properties of this form of dust are proved by the great disposition in this subvariety of pneumonokoniosis to the formation of fibrous nodules and diffuse areas of sclerosis in the lungs. The nodules have a gray center and a darker periphery; they are exceedingly dense, and sections are made with much difficulty.

(3) **Siderosis.**—This term implies a collection of iron oxid in the lungs, also due to the pursuit of certain occupations (dyeing, iron-smithing, etc.). Cases of much the same nature are caused by the inhalation of vegetable dusts by grain-shovellers, cotton-spinners, cigar-makers, etc. The *pathologic* changes are identical with those in anthracosis, though the color-appearance is red instead of black.

Symptoms.—Rarely the *onset* is marked by the symptoms of acute, followed by those of chronic, bronchitis; but in a vast majority of instances chronic bronchitis gradually develops after long exposure to the action of the exciting cause. The symptoms of emphysema are soon superadded, the patient now suffering from dyspnea, and less frequently from asthma. The *sputum* is diagnostic in anthracosis, being quite dark; in chalicosis a microscopic examination is essential to show the particles of silica; while in siderosis the expectoration presents a reddish color. Apart from the foreign particles, the sputum is for a long period of years muco-purulent in character, and later it often contains the tubercle bacillus.

The *physical signs* are not distinctive, being identical with those met with in chronic bronchitis associated with emphysema, and followed by those of interstitial pneumonia, and sometimes by those of cavity.

The **diagnosis** is to be made both from the history and from a gross or microscopic examination of the sputum. It may be confirmed by the invariable presence of the signs of bronchitis and emphysema, as well as by the effect of removal to an atmosphere free from dust. In the later stages the detection of infallible evidences of phthisis only serves to corroborate the earlier diagnosis of pneumonokoniosis.

An *acute pneumonokoniosis*, due to the inhalation of Thomas phosphate meal, has been described. This dust causes a diffuse pneumonic

inflammation affecting principally the lower lobes. The symptoms and progress of the cases are like those of lobar pneumonia.

The **prognosis** is favorable in hygienic surroundings until the more advanced stage is reached. The condition favors the invasion of new growths (lympho-sarcoma, or cobalt-miners' disease; *vide infra*).

Treatment.—A change of occupation or several hours of exercise in the open air daily for those who are exposed to dust in work-rooms should be advocated. Dusty work-rooms must be properly ventilated.

The active treatment is the same as for chronic bronchitis and emphysema from other causes, and is to be appropriately modified when pulmonary tuberculosis develops.

NEW GROWTHS OF THE LUNGS.

CARCINOMA OF THE LUNG.

ALL varieties of carcinoma have been met with in the lung, but, with rare exceptions, carcinoma of this organ is of secondary origin. Ordinarily the primary new growth involves a vein or lymph-channel, and the latter carries the germ of the disease to the lung. It is also to be recollected that it may result from extension, or by contiguity from neighboring organs (as the esophagus, mamma, pleura, or mediastinum).

Etiology.—The causes of primary carcinoma of the lung must be, in the main, identical with those of carcinoma in general, and are as yet unknown. Most cases occur in middle-aged persons, and, while sex has an influence upon the appearance of the primary form of the disease, it occurring much oftener in males, the secondary form is more frequent in the female than in the male. In the female, secondary carcinoma of the lung is often preceded by carcinoma of the breast. We may also regard hereditary influence as a potent predisposing factor. Secondary carcinoma of the lung is most commonly consecutive to primary carcinoma of the bones, and of the digestive and urinary tracts.

Pathology.—The pathologic varieties of the primary form are scirrhus, encephaloid, and epithelioma, and of these the latter is the most common. *Primary carcinoma* is usually unilateral, the tumors attaining to a massive size and frequently involving the greater part of one lung. Their favorite seat is in the upper part of the right lung. Extension to the pleura occurs quite often. Less frequently there is pleurisy with sero-fibrinous exudate, which may be hemorrhagic. Carcinomatous involvement of the cervical, bronchial, and tracheal lymph-glands is quite usual, and rarely even the inguinal glands become implicated. *Secondary carcinomata* are, as a rule, multiple, and may be miliary in size. They are disseminated widely throughout both lungs, though in the rarest instances they may be unilateral. In the softer varieties the central portion of the tumor-mass may undergo fatty degeneration, with subsequent discharge through adjacent bronchi.

Symptoms.—The symptoms vary according to the location and extent of the disease. Among the most marked symptoms belongs *pain*, particularly when the pleura is implicated. As a rule, for a considerable period of time the symptoms of *bronchitis* obtain, and later the breathing-

space is diminished sufficiently to excite dyspnea and cyanosis. With the increase in size of the new growth compression of the heart, aorta, and large veins may result, whereupon *disturbances of the circulation* will arise. The new growth may exert pressure on the esophagus, causing *dysphagia*; or upon the recurrent laryngeal nerve, causing *aphonia* and *hoarseness*; or on the trachea or a main bronchus, followed by the symptoms of *stenosis* of those organs. There are *cough* and *expectoration*, the latter frequently containing blood-corpuscles with mucus, and resembling in appearance currant-jelly; the sputa may also rarely exhibit a grass-green color, due to transformation of the blood-pigment. In carcinomatous lungs putrefactive changes sometimes take place, and if so the expectoration and breath emit an offensive odor, while a microscopic examination of the sputum frequently discloses the presence of carcinomatous elements. A leukocytosis, usually of moderate degree, may be present. The well-known cancerous cachexia invariably develops.

Physical Signs.—These will naturally depend upon the extent and location of the new growth. *Inspection.*—If the lung-tissue be extensively involved, the walls of the thorax become unduly prominent and fixed over the seat of the tumor. Indeed, the tumor may, though rarely, protrude between the ribs. The intercostal spaces are widened, and the superficial veins, in view of the fact that they cannot empty themselves into the internal veins, appear engorged; from the same cause edema affecting the thorax, neck, face, and arms may be noted. Swelling of the lymph-glands in the neck or axilla is an important sign. On *palpation* the tactile fremitus may be diminished or absent. The *percussion-note* will be flat, since the air-vesicles and smaller bronchi are replaced by the solid growth. On *auscultation* friction-sounds are the rule. The respiratory sounds may be greatly enfeebled or absent; but if the carcinomatous tumor communicates with a wide-mouthed bronchus, bronchial breathing may be audible, and the physical signs of lung-cavity may be developed. The signs of general bronchitis are present in most instances, especially in the disseminated form of the disease; in the latter the lung may shrink, with retraction of the chest-walls on the affected side. If secondary pleurisy with effusion occurs, the detection of the characteristic cancer-cells in the contents of the pleural cavity will show the nature of the thoracic affection.

Diagnosis.—The following symptom-group will pretty well establish a diagnosis: A peculiarly shaped dull area (as when it extends under the sternum), perhaps a marked prominence over the site of the tumor, enlarged and hard lymphatic glands in the vicinage, and certain of the compression-symptoms—circulatory, nervous, bronchial, or tracheal. Rarely the diagnosis may be made by the occurrence of metastasis to the chest-wall. Again, the discovery of cancer tissue in masses accidentally detached gives reliable indication of the disease. An exact diagnosis can often be made from an examination of the particles obtained on aspiration of the tumor.

The **differential diagnosis** between pulmonary carcinoma and *pulmonary tuberculosis* can be made with positiveness only by a careful microscopic examination of the sputum. From *fibroid induration* of the lung it is easily discriminated, owing to the history and slower course of the latter affection.

Prognosis.—This is bad, as death may occur suddenly from abundant hemorrhage or more frequently from either exhaustion or asphyxia. The duration of the affection varies from six months to a year, or, rarely, even two years.

Treatment.—The treatment must be addressed chiefly to the relief of pain and other subjective symptoms, though the effect of the *x-ray* should be tried.

SARCOMA OF THE LUNG.

Primary sarcoma of the lung is rare, but in instances of generalized sarcomatosis the lungs show larger or smaller nodules "in almost every case" (Birch-Hirschfeld), occurring in connection with osteo-sarcoma of other organs or in lympho-sarcoma of the cervical glands.

Secondary sarcoma, occurring in consequence of invasion of the root of the lung by sarcomatous disease of the post-bronchial glands, is more common than secondary carcinoma. The *diagnosis* is reached as in carcinoma (*vide* p. 576).

Neoplasms occurring among the cobalt-miners of Schneeberg were described by Hesse and Tragner as lympho-sarcomata—slowly growing masses that attained to a large size and gave metastasis to lymph-glands, pleura, liver, and spleen. In most cases there was an associated pneumokoniosis, which had probably predisposed to the new growth.

HYDATID CYST OF THE LUNG.

Hydatids in the lungs may either be primary or secondary, the former variety being exceedingly rare and the latter somewhat less so. Almost invariably the echinococci are developed in other organs—the liver in particular—and find their way to the lungs, either by direct perforation through the diaphragm or by entering through the blood-current. The lungs are involved in about 12 per cent. of hydatid disease.

For **etiology** and **pathology** see Hydatid Cysts of the Liver.

Symptoms.—The clinical manifestations are quite varied, even though the cyst may entirely conceal itself. It is important to recollect that similar involvement of the liver usually coexists; and in addition to the symptoms of the latter affection there may be *pain* in the chest, *dyspnea*, considerable *cough*, and, rarely, blood-stained *expectoration*.

The **physical signs**, when present, are as follows: Diminished vocal fremitus, defective expansion, dulness on percussion with an absence of the respiratory murmur—all signs pointing to pleural effusion. The cysts are more common in the right lung and frequently cause marked bulging over the base. Later signs of cavity-formation may appear. In other cases, the signs of consolidation may preponderate.

A positive **diagnosis** of hydatid cyst of the lung can be made only when the scolices, pieces of membrane, or the hooklets of the echinococcus are demonstrable either in the sputum or the aspirated fluid. Besides being evacuated into the bronchi, the cysts may rupture into the adjacent serous sacs (pleura, pericardium), or externally, the latter being the most favorable termination. Unless they are discharged by ulceration into the bronchi or externally, they are apt to excite inflammation of the adjacent lung-tissue and tubes, accompanied by an active febrile movement and an aggravation of the aforementioned symptoms: these

complications (pneumonia, gangrene) may assume a dangerous form, or the patient may, if the growth attains large dimensions, become asphyxiated. From *gangrene*, *pleurisy*, and *phthisis* echinococci are distinguished by the sputum-test or by an examination of the aspirated fluid.

Prognosis.—The affection is always attended with great danger, and is of more serious import when secondary to involvement of the liver than when primary.

Treatment.—When it can be shown that the growths are situated at the periphery of the lung operation should be carefully considered. The physician stands powerless to do more than to relieve urgent symptoms in special cases and to support the vital functions.

V. DISEASES OF THE PLEURA.

PLEURISY.

(*Pleuritis*.)

Definition.—An inflammation, either local or general, of one or both pleural membranes. The disease, as shown by postmortem examinations, is of great frequency.

Varieties.—Pleurisy has been variously classified. *Etiologically*, the distinction between primary and secondary forms of the disease should be made, as well as a division into tuberculous, carcinomatous, septic, etc. *Pathologically*, all cases may be summarized under the following heads: Localized and generalized and dry (plastic) pleurisy and pleurisy with effusion (sero-fibrinous, purulent, hemorrhagic). They may also be classified according to their duration into acute, subacute, and chronic pleuritis. I shall describe the following forms, which are based partly upon their etiology and clinical course, though mainly upon their pathologic manifestations—viz. (a) acute plastic pleurisy; (b) sero-fibrinous pleurisy; (c) purulent pleurisy (empyema); and (d) chronic adhesive pleurisy.

Bacteriology.—In all forms of the disease the *direct* causes are various micro-organisms or their irritating chemical products. Conspicuous among these is the *bacillus of tuberculosis*. Inoculation of guinea-pigs with the latter by Eichhorst gave positive results in 15 out of 23 cases, and by La Damany in 47 out of 55 cases. By taking a large amount of exudate either for cultures or inoculation of animals, the bacillus tuberculosis can be found, as a rule. Netter, Prudden, and others have found in the exudation of *fibrino-serous pleurisy* the *streptococcus pyogenes*, the *staphylococcus*, the *typhoid bacillus*, and the *diplococcus of pneumonia*. The micro-organisms most commonly present in *empyema* are the *micrococcus lanceolatus* and the *streptococcus*, the former especially in the pleurisy associated with pneumonia (in two-thirds of the cases occurring in children—Levy), and the latter in those independent of pneumonia, particularly in adults. Among other bacteria that have been found rarely in the effusion are the *colon bacillus*, the *proteus*

vulgaris, the *gonococcus*, the *ameba coli*, *Friedländer's bacillus*, *anthrax bacillus*, *influenza bacillus*, and various saprophytic bacteria. Except in the case of the pleuritic exudation (usually purulent) in pneumonia, in which the diplococcus is alone present in about one-half of the cases, the afore-mentioned microorganisms are generally found in association.

ACUTE PLASTIC PLEURISY.

(*Dry, Fibrinous Pleurisy.*)

Pathology.—The lesions are usually circumscribed, the part inflamed being intensely injected. It has lost its natural lustre, and instead has a dull, non-glistening surface “like a tarnished mirror,” due to a slight fibrinous exudate. Minute ecchymoses are seen. Later the exudate may become more copious, when the pleura presents a rough, shaggy appearance. On account of the friction between the two pleural membranes in high grades of dry plastic pleurisy, the exudate may be very thick, and its color-appearance is then yellowish- or reddish-gray. This sheeting of fibrinous exudate entangles in its meshes numerous embryonic round cells, out of which blood-vessels and connective tissue are developed. The opposing surfaces of the pleura adhere. Occasionally, in the lighter grades, the disease does not advance to firm adhesion, and in such instances the products of the exudate undergo fatty degeneration and are absorbed.

Etiology.—The affection may be (a) primary or (b) secondary. (a) By the *primary form* is meant an inflammation of the pleura occurring in previously healthy persons. It is exceedingly rare, and doubtless many instances of true secondary pleurisy are regarded as belonging to this category. Aschoff's studies of 200 cases of pleurisy showed 41 to be idiopathic. Of great etiologic prominence is exposure to cold and wet, and next to this stands mechanical injury. It is more common in men than in women, and especially during the time of active life, on account of the greater liability to exposure of the former sex. In almost all instances a careful search will disclose the existence of some diathesis (tuberculous, gouty, rheumatic) that may be properly regarded as the favoring cause. The changeable weather of the winter and spring augments the proportion of cases during these seasons as compared with summer and autumn.

(b) The *secondary form* of dry plastic pleurisy arises from extension of acute and chronic inflammatory affections of the lungs and other neighboring organs. Hence it frequently follows croupous pneumonia, somewhat less frequently broncho-pneumonia, and more rarely still hemorrhagic infarct, abscesses, and pulmonary carcinoma and gangrene. When pleurisy occurs on the right side it must be recollected that it may have originated in hepatitis. Plastic pleurisy sometimes arises in acute articular rheumatism, to which it may essentially belong. It is an almost constant accompaniment of chronic pulmonary tuberculosis, and may, though rarely, even constitute the primary lesion (primary tuberculous pleurisy). The disease may appear as a complication in chronic alcoholism and in chronic Bright's disease. Finally, inflammation of other serous membranes, as of the pericardium and peritoneum, by direct extension through the lymphatics may invade the pleura.

Symptoms.—The affection may vary in intensity between the extremes of mildness and great severity, though, as a rule, well-marked local symptoms attend the onset. Among the latter a *sharp "stitch" in the side*, that is usually referred to the nipple, is the most prominent. The *pleural pain* is increased by inspiration as well as by voluntary motion of the affected side, and hence the patient assumes a fixed position in which he favors the affected side by leaning toward it. There is a dry, distressing *cough* that is restrained for obvious reasons, and the *respiration* is somewhat hurried, painful, and jerking in character until the exudation is poured out, when relief from this and other local symptoms ensues.

The general symptoms are not pronounced, and, save in comparatively rare instances, do not correspond with the local signs. The temperature is not typical, rarely exceeding 103° F. (39.4° C.), and more often it is below 101° F. (38.3° C.). The pulse is usually small and tense or soft in character, registering from 90 to 120 beats per minute. Not infrequently the cases are so mild as to be attended by few, if any, subjective symptoms. The patient may complain of ill-defined, uneasy sensations in the affected side, but does not discontinue his usual occupation. On the other hand, the worst cases of acute plastic pleurisy—which, fortunately, are rare—manifest violent symptoms: there is a distinct chill, a speedy development of high fever (104° F.—40° C.), and profound prostration, and the general and local symptoms are proportionately aggravated. The illness then is often a fatal one.

Physical Signs.—On *inspection* the movements of the chest-wall on the affected side are observed to be much restricted, particularly during the first day of the affection. *Palpation* confirms the results of inspection, while *percussion* yields a normal note. *Auscultation* renders audible a grazing friction-sound, most intense at the end of inspiration. These signs are not uncommonly situated at the apices.

With the occurrence of fibrinous exudation *palpation* detects over the corresponding area a diminution of the tactile fremitus. On *percussion* there is, as a rule, a slight though variable degree of dullness; and on *auscultation* rubbing friction-sounds or a rustling sound due to fine râles are heard both on inspiration and expiration, being intensified by deep breathing. These sounds frequently persist for a day or two after the other symptoms have disappeared. Rarely the plastic exudation may be so extensive as to cause compression of the lung, in which instance the breath-sounds may become bronchial in character; and such cases have been mistaken for lobar pneumonia.

Diagnosis.—By exercising ordinary care the clinician can scarcely mistake other thoracic affections for dry pleurisy, the latter being diagnosed to a certainty by the presence of the characteristic friction-murmur. *Intercostal neuralgia* may present features not unlike those of acute pleurisy. In both affections there is frequently a history of exposure, followed by severe chest-pains that are excited by coughing and deep breathing. In neuralgia, however, there are painful pressure-points, and the pleuritic friction-sound does not occur. *Pleurodynia* may also give a history very similar to that of acute pleurisy, but the characteristic physical signs of pleurisy are absent.

Prognosis.—The duration of the affection varies from a few days

to three weeks, and the immediate outcome is favorable as a rule. Undoubtedly, however, a primary attack predisposes to subsequent attacks, and thus, as a result of repeated seizures, pleural thickening and intrapleural adhesions often arise. Lung-expansion may in this manner be restricted, with the gradual development of interstitial pneumonia as a consequence. Acute plastic pleurisy is not infrequently a terminal condition in serious forms of illness (*e. g.*, septicopyemia and chronic nephritis).

Treatment.—The first object in the treatment is to relieve the pain, and this can best be accomplished by the hypodermic use of morphin. The inflammatory process is best controlled by absolute *rest* in the recumbent posture, allowing the patient to assume that position which gives him most comfort. I am also in the habit of administering moderate-sized doses of quinin (gr. iv—0.259—three times daily). After the exudation has appeared, the iodids of iron and potassium, in combination, may be employed. *Locally*, nothing is so effective as cold in the form of the ice-water bag or Leiter's coil, preceded, in robust patients, by the local abstraction of blood (3ij to vj—96.0–192.0) by leeches. At the end of one week the morphin may usually be discontinued. During *convalescence* the patient should be instructed to take deep inspirations several times in succession, not less than a dozen times each day, with a view to obviating as far as possible pleural adhesions and other unfavorable consequences. Symptomatic anemia may be present at this time, and should be met by iron given internally. At this time iodin may be used locally with great benefit; I have not, however, seen any favorable results from blisters. For the pain which continues in the side after all detectable physical signs have disappeared the use of the constant current over the seat of the pleurisy for twenty minutes at a time gives almost instantaneous relief (Loomis).

SERO-FIBRINOUS PLEURISY (PLEURISY WITH EFFUSION, SUBACUTE PLEURISY).

Pathology.—During the first stage of sero-fibrinous pleurisy the changes are the same in character as those met with in dry pleurisy, though of severer grade, and usually involving the greater portion of the pleura on the side affected. There is an abundant exudation of serum, and usually the entire pleura becomes coated with a fibrinous exudate, that varies greatly in thickness and arrangement. The exudate is thin and smooth in some instances, though more frequently it forms a thick layer, presenting a shaggy surface on the one hand or an irregular, honeycombed surface on the other. Lymph in the form of flocculi is rather abundant in the serous effusion. The interlobular pleural surfaces are also invaded as a rule, in consequence of which they become adherent. The fluid exudate varies greatly in quantity ($\frac{1}{2}$ to 8 pints—4 liters), is often of a citron color, and is, in the majority of instances, clear or slightly turbid. Rarely it is of a dark-brown color.

Unless adhesions between the pleural surfaces have previously existed the effusion gravitates to the most dependent portion of the pleural cav-

ity. Microscopically, there are found leukocytes, red blood-corpuscles, endothelial cells, threads of fibrin, and, rarely, crystals of cholesterolin and uric acid. The composition of the fluid is almost identical with that of blood-serum, and on boiling it is found to be rich in albumin. Spontaneous coagulation may take place on standing.

Changes in the Neighboring Organs.—So long as the normal retractility of the lung is not overcome by the fluid that collects in the pleural cavity, the latter does not produce positive intrathoracic pressure, and hence does not produce displacement of adjacent organs. It may be assumed that until the pleural sac is at least one-half filled with sero-fibrinous exudate the natural contractility of the lung is not destroyed. At this period there may be a slight displacement of the mediastinum toward the opposite side, due to traction exerted by the normal retractility of the sound lung. Obviously, large effusions must in a mechanical manner displace the pleural membranes, thus causing compression of the pulmonary structures lying above the effusion. A very copious effusion may push the lung up and back against the vertebral column and convert it into a small, flat, bloodless, and airless mass (atelectasis). While a total absence of air in the collapsed lung is due chiefly to compression by the fluid, to some extent, however, the air may be absorbed by the vessels or even by the effusion (Strümpell).

Together with compression of the lung by the effusion, pressure is also exerted by the latter against the mediastinum, causing displacement of the heart. The mediastinum also loses the normal traction-force of the lung upon the affected side, and hence the lung on the sound side draws the mediastinum toward itself by its own retractile energy. Osler shows that even in the most extensive left-sided effusion the heart's apex is not rotated, but that the normal relative position of the apex and base obtain, though the apex is in some instances lifted, and in others the heart lies more transversely. The right chambers of the heart occupy most of the anterior part of the organ, showing that the displacement of the mediastinum with the pericardium and its contents to the right involves no appreciable twisting of the heart itself.

Downward displacement of the diaphragm takes place in extensive effusion on the right side, depressing the liver to a variable distance below the inferior costal border; on the left side large effusions produce pressure-displacement of the stomach and the transverse colon, and, to a slighter extent, of the spleen. Pre-existing adhesions may prevent displacement of the adjacent organs.

Etiology.—The causative factors are identical in nature with those producing dry plastic pleurisy. It is highly probable that the degree of severity is dependent upon the previous condition of the patient, whether he be suffering from some other affection or not, and upon the amount of specific poison gaining access to the pleura.

The affection may be *primary*, but is much more often *secondary*, and this fact may be explained by reference to any of the specific micro-organisms producing the affection.

Direct Causes.—Many of the cases follow quickly upon exposure to cold or wet or an injury to the thorax. I thoroughly agree with those authors who contend that about three-fourths of the cases of sero-fibrinous pleurisy are of tubercular origin. The tuberculous process may invade

the pleura primarily, but more often it is secondary to tuberculosis of the lungs; less frequently, though oftener than is generally supposed, it is secondary to tuberculous peritonitis. In these instances the tubercle bacilli probably find their way from the peritoneum to the pleura by traversing the lymphatics in the diaphragm. A large percentage of apparently primary cases of tuberculous pleurisy have their origin in a circumscribed and more or less latent tuberculous focus in the lungs. It is not improbable also that tuberculous processes in other viscera may furnish the tubercle bacilli for secondary pleural infection. Moreover, the fact that many cases of sero-fibrinous pleurisy recover does not disprove their tuberculous nature.

The affection is not infrequently secondary to acute articular rheumatism, which is itself most probably a microbic affection. It also arises as a complicating condition in the course of various acute and chronic affections of the chest, as pericarditis and catarrhal pneumonia, and may develop in acute infectious diseases, as typhoid fever or lobar pneumonia. The typhoid bacillus of Eberth has also been known to provoke pleurisy (Bozzolo, Fernet, and others).¹ It may occur as a complication in the chronic affections of various viscera (chronic nephritis, cirrhosis and carcinoma of the liver). The *predisposing causes* are the same as for the dry plastic form.

Symptoms.—The description here refers particularly to primary sero-fibrinous pleurisy, and it is important to recollect that when secondary to other acute and chronic affections characterized by great bodily weakness the pleuritic symptoms may be in abeyance.

With few exceptions the onset is *insidious*, the symptoms being quite mild; but rarely there is a *sudden onset* with active symptoms (rigor, high fever). In the majority of instances the patient first complains of a *stitch-like pain* in the side; this is rarely pronounced, but is aggravated upon deep breathing and upon any muscular exertion. *Dyspnea* soon arises and gradually increases in intensity. *Cough* may be present or absent, and in some instances is attended by a scanty mucoid expectoration that may rarely be blood-streaked.

The *constitutional symptoms* are of correspondingly slow and gradual development. From the commencement of the attack a moderate febrile movement at night may be observed, and the pulse will be found to be frequent, small, and compressible, or, more rarely, tense. At the time of the patient's first visit to his physician he may give a history of having gradually lost flesh and strength for a period of weeks together, though he may not have been obliged to abandon his vocation. He looks pale, his countenance wears an anxious expression, and he is without appetite. These cases frequently drag on from two to four weeks before consulting a physician, the local symptoms going unnoticed.

Sometimes the period of invasion develops acutely and after lasting a few days the symptoms exhibit a decided remission; subsequently there may be a sudden recurrence of the local and general phenomena, and particularly of the dyspnea. The pleural cavity, which may have been one-half or two-thirds full, now becomes completely filled.

Special Symptoms.—*Pain.*—Chest-pain is an almost constant but not highly characteristic symptom, and, though usually among the earliest symptoms, it may not be present until a few hours or a day after the

¹ *Annual of the Universal Medical Sciences*, vol. ii., p. 12.

commencement of the affection. It may be described as a sharp, shooting pain, and is popularly termed a "stitch in the side." It may, however, be tearing or dragging in character. Its intensity is not a safe indication of the severity of the disease. It is usually referred to a small spot below the nipple or to the mid-axillary region; exceptionally, however, it is more diffuse, and in my experience it has not infrequently been retrosternal or referred to limited areas below the inferior costal border. When absent it may be excited by coughing, sneezing, deep inspiration, and stooping. With the appearance of the effusion the pain diminishes, and, as a rule, soon disappears.

Dyspnea.—The breathing is shallow, "catching," inspiration being made up of a series of gasps, and it is hurried in consequence of the severe pleural pain; in copious effusions, that render one lung functionless, the dyspnea may become intense, even attaining to orthopnea. It reaches its most pronounced form in previously robust subjects, and in those in whom the effusion has developed rapidly. On the other hand, when the pleural sac fills slowly dyspnea may be absent except on exertion. Following marked disturbances in the respiration, *cyanois* appears and may become quite marked.

Cough and Expectoration.—Little need be added to what has already been stated. When there is present much expectoration it is not uncommonly due to associated bronchitis or to pulmonary tuberculosis; there may, however, be a total absence of expectoration, and in such instances the exciting cause of the cough is probably the pleuritis. Both the cough and expectoration are apt to be increased during the process of resorption of the exudate as the result of a catarrhal bronchitis that is prone to develop in the re-expanding lung.

Fever.—The rise of temperature is not rapid as a rule, nor does it reach a high point (101.5° to 103° F.— 38.6° – 39.4° C.). At the end of a variable period—usually one to three weeks—the temperature falls by lysis, and soon touches the normal. The temperature may be of the continued type in many acute cases. In subacute forms the temperature rarely rises above 101° F. (38.3° C.), or the fever may, finally, become hectic. The surface-temperature of the affected side is from one-half to two degrees (0.4° – 1.6° C.) higher than that of the normal side.

Pulse.—The pulse is quickened, beating 100 or more per minute, and its volume and tension are diminished. Irregularity both of the volume and rhythm of the pulse may also be observed. These pulse-characteristics are to be attributed to the pressure of the effusion upon the heart and great vessels. There is a leukocytosis in non-tuberculous pleuritis, although the increase in the white cells is moderate.

Gastro-intestinal Symptoms.—Loss of appetite is commonly present, and more rarely nausea and occasional vomiting may arise at the outset. Constipation is the rule. *Sweating* is a common symptom in the more protracted cases.

Renal Symptoms.—The amount of urine is diminished both during exudation and while the exudate remains at its maximum level. The daily quantity may not exceed eight or ten ounces, but the specific gravity is increased, ranging from 1018 to 1028. Rarely, the quantity is increased with existing effusion. An increase in the daily amount of urine excreted is frequently the first sign of commencing absorption of the exudate, and the rapid resorption of the copious effusion may greatly

augment the flow of urine to 80 or 100 ounces (2.5 to 3 liters) daily (Strümpell). The cause of the diminished secretion of urine is, in the main, diminished arterial pressure.

Physical Signs.—The physical signs of sero-fibrinous pleurisy differ with the stage of the affection: those of the first stage are identical with the signs pointed out in connection with dry plastic pleurisy, and need not be restated here. We will note the physical signs (1) during the stage of effusion, as well as (2) those presented when absorption of the effusion has taken place.

(1) *Stage of Effusion.*—When the pleural sac is only partly filled there is noted, on *inspection*, but little change in the thoracic contour. The respiratory movements are, however, restricted, owing to mechanical hindrance to the lung-expansion. In the majority of instances the effusion increases until positive intrathoracic pressure and noticeable bulging in the middle and lower third of the chest-wall on the affected side take place; the intercostal spaces below are shallow, widened, and sometimes even effaced. The apex-beat of the heart is displaced, being visible in right-sided pleurisy to the left of the vertical mammary line in the fourth and fifth interspaces, and in left-sided pleurisy to the right of the right mammary line in the third and fourth interspaces. The apex of the heart may take a position behind the sternum, when no impulse will be visible. In moderate effusions rhythmic lateral displacement of the heart (which approaches the affected side during inspiration and moves outward in expiration) occurs (C. L. Greene). Litten's phenomenon, or the shadow of the diaphragm, is absent in this disease.

Palpation.—The limited range of expansion is readily appreciated on palpation, and in large effusions the chest-wall is practically fixed. The separation of the ribs and the obliteration of the intercostal spaces are easily made out in the same manner. Edema of the chest-wall is rarely present, and fluctuation almost never. An important and early physical sign is the diminished tactile fremitus, which is soon abolished, except in infants, in whom it may be excited on crying. This is a less valuable sign in women than in men, owing to the differences in the vocal vibrations in the two sexes. In copious effusions tactile fremitus may sometimes be obtained when bands of adhesion, which serve as a medium for the transmission of vocal fremitus, connect the pulmonary with the costal pleura. The apical impulse can also be readily located by palpation. The displaced spleen or liver can be felt through the abdominal wall, and must not be mistaken for an actual enlargement of these organs.

Mensuration.—In right-handed adults the right side is, normally, slightly larger than the left; and it is only after the effusion is considerable that the cyrtometer shows any alteration in the thoracic contour. The tape, however, exhibits the difference in expansive motion of the two sides early. At the end of expiration the circumference of the affected side will be found to be one or two inches greater than that of the unaffected side, while at the end of inspiration the difference will be but slight. The cyrtometric tracing also shows a discrepancy between the horizontal outlines of the two sides.

Percussion.—At first the percussion-note is impaired, either posteriorly or in the infra-axillary region, and a little later there is dullness, tending toward flatness (deadness), the upper level of which rises

from day to day with increasing effusion. Over the exudate the note has a wooden quality (flat) and there is great resistance. When the effusion rises to the fourth rib anteriorly there is dulness over the fluid above and absolute flatness below. Since both the flatness and dulness are due to the free fluid, it is obvious that the line of demarcation must change with the posture of the patient; hence the limit of dulness will be higher in the sitting than in the recumbent position. When the pleural sac is filled or when the effusion is confined by adhesions, movable dulness is not obtainable. When the exudate rises to the lower border of the third rib, the percussion-note above the line of dulness is tympanitic or vesiculo-tympanitic (*Skoda's resonance*); this holds also in more moderate effusions, and is attributable to mediate relaxation of the lung. In copious exudations the cracked-pot sound may be elicited immediately below the clavicle, and "*Williams's tracheal tone*" may sometimes be obtained. This may also be obtained at a point corresponding to the seat of the compressed lung. When the patient is sitting or in the erect posture the upper limit of dulness in large effusions is not a horizontal line, but is highest at the spine and falls as we proceed to the front, which is its lowest point. The upper line of dulness in moderate effusions begins "relatively low down in the back, passes upward from the vertebral column, and soon turns upward and proceeds obliquely across the back to the axillary region, where it reaches its highest point; thence it advances in a straight line, but with a slight descent, to the sternum" (Ellis). This curved line resembles the italic letter *S* (Garland). Grocco's sign (a triangular area of dulness over the back on the opposite side in unilateral pleurisy, which dulness disappears when the patient lies on the side of the effusion) is confirmatory, although it is not invariably present. On the right side the flatness is continuous with that of the displaced liver; on the left it passes into and may obliterate Traube's semilunar space.

Auscultation.—The signs of the first stage have already been described (*vide* Plastic Pleurisy). With the appearance of the effusion the breath-sounds become weak, distant, and have a bronchial quality. Soon the respiratory sounds over the affected side will be entirely absent, except near the upper level of the fluid posteriorly, where distant bronchial breathing is audible. The latter sounds may exhibit a metallic or amphoric quality, and may be accompanied by râles (pseudo-cavernous signs). The latter are more frequently met in children than in adults, and often give rise to a false diagnosis. Above the level of the fluid there is broncho-vesicular breathing, and on the opposite side intensified breath-sounds may usually be noted. In pneumonia with pleural effusion there may be loud and persistent bronchial respiration over the exudate. The vocal resonance is diminished and may manifest a nasal quality, simulating somewhat the bleating of a goat (*Laennec's egophony*). This is best obtained near the upper level of the fluid in large effusions, and at or above the angle of the scapula when the effusion is moderate.

(2) *Stage of Resorption*.—With resorption of the fluid there is a decrease in the size of the affected side, together with a return of the normal appearance of the intercostal spaces and the respiratory movements. In many instances there is positive retraction, leading to thoracic deformity with displacement of neighboring organs toward the affected side; and this retraction may be either general or circumscribed. The infe-

rior intercostal spaces are more or less narrowed; the shoulder droops; the nipple approaches the median line; the spine may be curved, the convexity being directed toward the sound side (quite rarely toward the affected side); and the scapula projects from the chest-wall on the affected side. In children, and even in adults, the lungs and thorax gradually expand in order to overcome this chronic deformity.

Palpation.—The tactile fremitus closely follows the fluid as it subsides from above downward without any extreme degree of thickening of the pleural membranes, though cohesion of their surfaces may prevent its return over the lower segment. The inspiratory movement of the chest-wall gradually returns, but not to its former limit.

Mensuration shows a steady diminution in the size of the side involved, which finally becomes smaller than its fellow.

Percussion.—The dull or flat note gives way to normal percussion-resonance, proceeding from above downward in a gradual manner; but the latter is not renewed over the lower portion of the pleural cavity for a long period after the exudation has disappeared. The abnormal areas of flatness due to displacement of organs (liver, spleen, heart) also disappear.

Auscultation discloses most important signs during the stage of absorption. The breath-sounds reappear at first above, and then lower down, until the base is reached. With commencing subsidence of the fluid the respiratory sounds are feeble and distant, but later they resume their natural distinctness; and partly as a result of the revival of the natural muscular tonicity, and partly in consequence of the disappearance of the fluid, the two roughened pleural surfaces come in contact and play upon one another, giving rise to a rubbing, creaking friction-sound on auscultation. These friction-murmurs may persist for months after the effusion has been absorbed. Occasionally the lower portion of the compressed lung remains permanently inexpandible; the upper portion of the lung is now the seat of compensatory emphysema. The heart-sounds return to their normal position.

X-rays.—Williams¹ states when the effusion is large no more rays pass through it than through the liver, and the outlines of the diaphragm, ribs, and heart are obliterated on the side of the effusion. The fluoroscope also shows the direction and extent of cardiac displacements due to pleural effusions. Williams affirms that displacement of the heart to the right may not be recognized by percussion, even when it has been pushed much beyond its normal place. Displacement of the pleuritic fluid when the patient's position is changed and also with the movements of the diaphragm has been noted with the fluoroscope (Bergoné and Carrière).

Special Clinical Forms of Acute Sero-fibrinous Pleurisy.—

(1) *Tuberculous Pleurisy.*—This is, in the majority of instances, secondary to pulmonary tuberculosis. On the other hand, the primary lesions may be situated in the pleural sac and give rise to (a) *Acute sero-fibrinous pleurisy* (with the usual course); (b) *Subacute pleurisy* (with insidious course), leading to tuberculous invasion of the lungs; and (c) *Chronic adhesive pleurisy*, in which the course and physical signs correspond with those to be depicted in a special section on Chronic Pleurisy.

The morbid lesions are similar to those met with in other forms, plus the specific tubercles, which may be exceedingly numerous (miliary

¹ *Philadelphia Medical Journal*, January 6, 1900.

tubercles) on the one hand, or confined to a few circumscribed areas on the other. This variety has no special etiologic connection with empyema, and the effusion is usually sero-fibrinous and often blood-stained.

It should be pointed out that tuberculous pleurisy is sometimes followed by tuberculous pericarditis or peritonitis, or both. The two latter affections have been considered elsewhere (*vide* p. 279). We must grant that tuberculous pleurisy may proceed favorably with apparent recovery, though too often, after a variable interval of time, tuberculous symptoms are manifested. R. C. Cabot obtained the subsequent histories in 221 cases of pleural effusion in the Massachusetts Hospital; he followed them five years until phthisis or death took place in 117; at the end of five years 96 had recovered. It is found that about 30 per cent. become tuberculous.

(2) **Diaphragmatic Pleurisy.**—This term is applied to those instances in which the diaphragmatic portion of the pleura is involved, either alone or in part. There occurs an exudate that may be either plastic or sero-fibrinous, though rarely large in amount. The *symptoms* are acute, and the pain, which is lancinating in character and situated in the epigastric region, is the most prominent feature. Geuneau de Mussy¹ holds that pain along the tenth rib, extending from the anterior extremity to the sternum and xiphoid cartilage, is pathognomonic. It is increased by deep inspiration and by pressure over the insertion of the diaphragm at the tenth rib, and often abates when effusion takes place. Dyspnea is a marked symptom in most cases, and the patient may be forced to assume a stooping or sitting posture, the respirations being superficial, purely thoracic, and "catching." Cough, nausea, and even vomiting, may occur. In a case under my own care vomiting, due most probably to associated peritonitis, was a troublesome symptom.

The *constitutional features* are quite pronounced, particularly the fever, which exceeds that met with in other forms of pleurisy. The patient's anxiety is extreme. The effusion may be purulent, and if so bulging of the lower intercostal spaces, followed by edema, may occur.

The physical signs are for the most part negative.

(3) **Encysted Pleurisy.**—This term has reference to effusions that are circumscribed in consequence of adhesions between the pleural membranes. There may be two or more pouches, with or without communication. This so-called encapsulated pleurisy may occupy any part of the chest, and is exceedingly variable in extent. The symptoms and physical signs are rarely trustworthy for diagnosis, but should usually afford ground for suspicion, and lead to an exploratory puncture.

(4) **Interlobar Pleurisy.**—This variety is usually secondary to, or associated with, the ordinary type of acute sero-fibrinous pleurisy. The serous surfaces between the lobes are involved in the inflammatory process, and the fluid becomes encapsulated in this position in consequence of interlobar pleural adhesions. It is more frequent on the right than on the left side, and its favorite seat is near the root of the lung, between the upper and middle lobes. Osler² met with a case following pneumonia in which there was between the lower and upper and middle lobes of the right side an enormous purulent collection that looked at first like a large abscess of the lung. Fistulous connection with a bronchus often occurs, and the purulent expectoration that follows may be the first

¹ *Arch. gén de Méd.*, 1853, vol. xi., quoted by Fox.

² *Practice of Medicine*, p. 567.

symptom to attract attention to the process of suppuration in the thorax. Prior to the occurrence of this accident the patient presents indefinite symptoms. The patient may or may not give a clear history of antecedent pleurisy. These cysts contain, as a rule, but a small amount of fluid, and cause little bulging of the intercostal spaces. Indeed in a case of my own at the Philadelphia Hospital there was actual retraction, though the aspirating needle showed the presence of effusion.¹

(5) **Hemorrhagic Pleurisy.**—By this term is meant an admixture of

FIG. 48.—Illustrating pleurisy with effusion: 1, compressed lung-tissue, giving dull tympany on percussion; 2, fluid exudation obliterating intercostal spaces; 3, depressed liver; 4, displaced heart.

blood with the exudate in acute sero-fibrinous pleurisy, in quantities sufficient to be detectable by the unaided eye. The condition must be separated from *hemothorax*. The causes of hemorrhagic pleurisy are—(1) Tuberculous infection, either of the miliary or the chronic (circumscribed) form, following tuberculous disease of the lung; (2) Carcinoma of the pleura; (3) Bright's disease and cirrhosis of the liver; (4) Adynamic states

¹ *International Clinics* (1894), vol. i., p. 39.

of the system associated with malignant forms of acute infectious diseases (pneumonia). (5) Advanced age and alcoholism.

The fact that it may be engendered by an accidental wound of the lung during thoracentesis must be remembered.

Diagnosis.—In diagnosing pleurisy our attention must be directed chiefly to the physical signs. Unfortunately, the rational symptoms are often too slight to call attention to the chest. The diagnosis should embrace the particular etiologic variety (*e. g.*, tuberculous pleurisy, streptococcus, or pneumococcus pleurisy), by a bacteriologic examination of the exudate. The chief difficulties are encountered in distinguishing this affection from conditions in which the lung is either consolidated, retracted, or compressed by solid new growths or a serous transudate. Chief among the former is *croupous pneumonia* (especially in pleuritic exudates of moderate degree), and I have tabulated below the most important distinctions between it and pleurisy. The reader will be further aided by comparing Fig. 48 with Fig. 12, on page 122, since these show the physical conditions in the two diseases.

PLEURISY WITH EFFUSION.

PRIMARY LOBAR PNEUMONIA.

Rational Symptoms.

Onset marked by chilliness, persisting for a few days.

The pain is sharp, "stitch-like," and strictly localized.

Cough irritating; no expectoration, or catarrhal.

Sputum rarely shows tubercle bacillus.

Moderate fever of continuous type; decline by lysis.

Systemic prostration (moderate).

Countenance pale and anxious.

Herpes does not appear.

Leukocytosis absent or slight.

Onset acute, rigor, lasting one hour.

Acute pain (similar), but soreness more diffused.

Cough more marked and accompanied by rusty or bloody expectoration.

Shows presence of pneumococcus.

Intense fever; decline by crisis from the fifth to the ninth day.

Prostration marked.

Countenance congested; mahogany flush on the cheeks.

Herpes quite common.

Leukocytosis usually marked.

Physical Signs.

Inspection.

Distention of the thorax.

Palpation.

Diminished or absent tactile fremitus.

None.

Marked tactile fremitus (absent only when a bronchus is plugged).

Percussion.

Flatness, with great resistance to the pleximeter-finger.

Shows displacement of neighboring organs. Grocco's sign usually present.

If the sac be partly filled, line of flatness changes on varying the position.

Dulness less wooden, less resistance, and sometimes a tympanic note.

No displacement of neighboring organs, if uncomplicated. Grocco's sign absent.

Absent.

Auscultation.

Diminished or absent breath-sounds, bronchial breathing frequent, but diffused and distant and unaccompanied by râles, as a rule.

Vocal resonance diminished or absent; egophony.

Friction-sound in early and late stages

Harsh bronchial breathing and presence of râles in first and third stages, unless a bronchus be plugged.

Bronchophony (loud), unless a bronchus be blocked.

No friction-sound, except crepitant râles in the first stage.

Aspiration.

Yields serum.

Yields a few drops of thick blood.

Consolidation of the lung, due to tuberculous infection, may be differentiated by means of the physical signs contrasted in the foregoing table, the history of the case, and by the discovery of the tubercle bacillus in the sputum.

Hydrothorax presents physical signs that simulate strongly those of pleural effusion. Hydrothorax, however, gives the history of cardiac or renal disease, is oftener bilateral, and is unassociated with a rise in temperature or with the pain or friction-sounds peculiar to pleurisy. In hydrothorax the withdrawn fluid has a specific gravity below 1015, while that of the pleural exudate is above 1017. Iodine or its salts, administered by the mouth, are recoverable in large quantities, and within a short time in the transudate; whereas in the exudate only a trace is found (Rosenbach and Pohl's test).

Tumors and cysts of the thorax will give complete dulness, will displace the heart, and compress the lung on the affected side, thus causing an absence of the respiratory murmur, etc. But the history of the case, the situation of the dulness (usually over the upper or middle parts of the lung), and the absence of uniform distention extending to the base, will serve to distinguish these affections from pleurisy with effusion.

Echinococcus cyst of the liver, or *abscess* of this organ, pushing upward, will cause retraction or even compression of the lung, and produce most of the physical signs of pleurisy with effusion. The former affections can be discriminated only by a correct appreciation of the history, by the presence not infrequently of a friction-sound on auscultation, of Litten's sign, and by an immovably fixed upper convex boundary of dulness. If doubt remains, an exploratory puncture should be made, and the fluid withdrawn should be subjected to a chemical, microscopic, and bacteriologic investigation.

An *enormous pericardial effusion* may be mistaken for a pleural effusion on the left side. In the former, however, there is commonly a history of rheumatism, and dyspnea is an urgent symptom, while the heart-sounds are greatly enfeebled; moreover, the heart is not displaced to the right as in pleural effusion. Again, flat tympany is obtained in the posterior portion of the axilla and good pulmonary resonance at the base in the postero-lateral region of the chest in pericarditis.

For practical purposes it is desirable to distinguish the *tuberculous* from the rarer forms of pleurisy. This is possible by paying due regard to the previous history of the patient, including hereditary taint, by noting certain clinical peculiarities (such as associated disease of other serous membranes and of the lung), and by the results of an examination of the exudate. A high proportion (65–95 per cent.) of lymphocytes in the cells found in the effusion is indicative of tuberculous origin. Leukocytosis is absent in tuberculous pleuritis. The tuberculin reaction may be elicited in cases presenting but little fever. Inoscopy—*i. e.*, the digestion and centrifugalization of the previously coagulated exudate, often shows tubercle bacilli. In a dubious case the guinea-pig should be inoculated with the exudate, and if the patient be tuberculous positive results may be confidently expected.

Duration and Prognosis.—This depends largely upon the cause. The course of acute sero-fibrinous pleurisy is not definite, but is made up of two parts—the febrile followed by the non-febrile stage. The fever lasts from one to three weeks; it corresponds to the period when the effusion

occurs, and the appearance of a non-febrile period indicates the subsidence of the inflammation. The exudate may be poured out rapidly, and may be absorbed not less rapidly; more commonly, however, the effusion takes place rather gradually, and the same is true of resolution. The continued absence of bacteria in the pus speaks for tuberculosis. In individual cases the prognosis depends chiefly upon the bacteriologic cause (the outlook being especially bad in streptococcic pleuritis) or the gravity of the basal disease. Simple serofibrinous pleurisy, including the hemorrhagic variety, unless it appears as a complication in the later stages of some other grave disease, has a comparatively favorable prognosis. Death rarely ensues suddenly without adequate lesions to explain its occurrence. Moreover, the appearance of empyema renders the prognosis far less hopeful. Again, the crippling influence upon the lung-tissue of previous attacks, owing to resulting adhesions, must be borne in mind, since chronic bronchitis, emphysema, fibroid induration, and phthisis often supervene. Contrast between the temperature and physical signs is an unfavorable sign.

Treatment.—In the first stage the treatment is the same as for dry or plastic pleurisy. During the second stage, that of effusion, the objects of treatment are threefold: (1) To limit the extent and intensity of the inflammatory process; (2) to accomplish the removal of the effusion; and (3) to support the strength of the patient.

(1) **To Limit the Extent and Intensity of the Inflammatory Process.**—To this end two classes of agents are employed—namely, (a) *Internal*, and (b) *External*.

Among the latter are counter-irritants, as sinapisms and iodine, by means of which constant counter-irritation is to be maintained. Another agent of great worth is cold, applied by means of the ice-bag or ice-water bag, and if the temperature rises to 102° F. (38.8° C.) cool spongings of the surface of the body, together with the use of the ice-cap, are useful. Roberts recommended keeping the affected structures at complete rest to relieve the pain by mechanical fixation of the side affected. For this purpose strips of adhesive plaster must be firmly and evenly applied to the chest; they should be removed during the stage of effusion.

The *internal* remedies embrace quinine, the salicylates, and opium. Opium and quinine are potent in controlling inflammation of serous membranes; the former being given preferably either in the form of suppositories or hypodermically, and the latter in divided doses, in capsule, followed by a few drops of mineral acid, administering gr. xvj to xx (1.036–1.296) daily.¹ I have observed good results from the salicylates (3j–ij—4.0–8.0, daily), which have been warmly advocated by Fiedler, Koester,² and others, as valuable in mitigating or even aborting the inflammation of the pleuræ, and thus in limiting the amount of effusion. It must not be forgotten that the effusion is due to an inflammation, and not to a simple transudation. The use of mild diaphoretics and diuretics, coupled with repeated small doses of salines, also aids in reducing the inflammation in the pleura. With a subsidence of the inflammatory process the temperature falls, and then our efforts should be directed toward the fulfilment of the second leading indication, (2) the **removal of the effusion**.

Little is to be accomplished by local means, though iodine, persistently employed, sometimes does good. The following ointment may also be tried:

¹ *Internat. Clin.* (1892), vol. i, 2d series. ² *Ann. of Univ. Med. Sci.* (1893), vol. i. (A–31).

R \bar{y} . Ung. ichthyol. (12 per cent.),
 Ung. iodi comp., $\bar{a}\bar{a}$. $\bar{z}\bar{v}\bar{j}$ (24.0);
 Ung. belladonnæ, q. s. ad $\bar{z}\bar{i}\bar{j}$ (64.0).—M.

Sig. Apply twice daily.

Blisters are not admissible.

Mild hydragogue cathartics, and especially the salines, after the Matthew Hay method (*i. e.* $\bar{z}\bar{i}\bar{j}$ to $\bar{z}\bar{s}\bar{s}$ —8.0–16.0, in the smallest possible amount of water, on rising in the morning), stimulate absorption from the pleural cavities by draining the blood of a certain amount of serum. Unirritating diuretics may also be employed, but I have found no appreciable advantage from their use. Free diaphoresis (from the use of pilocarpin) sometimes assists in the absorption of the exudate, but it should not be employed in the presence of feeble heart-action or marked displacement of the organ. Among measures to promote absorption, the best, in my own experience, is the following combination:

R \bar{y} . Potassii iodidi, $\bar{z}\bar{j}$ (4.0);
 Syr. ferri iodidi, $\bar{z}\bar{i}\bar{j}$ (8.0);
 Syr. sarsap. comp., $\bar{z}\bar{j}$ (32.0);
 Ess. pepsini, q. s. ad $\bar{z}\bar{i}\bar{j}$ (64.0).—M.

Sig. $\bar{z}\bar{j}$ (4.0) every four hours, diluted; the dose to be doubled at the end of four days if well borne by the stomach.¹

Diuretin is sometimes of service in causing absorption of rheumatic effusions.

The patient should be put upon a dry *diet* in order to increase the plasticity of the blood, which is thus induced to absorb the liquid exudate from the pleural cavity. The *modus operandi* of this treatment is different, but the effect aimed at is the same as when saline purgatives are given. Gilbert and Fede advocate autoserotherapy to stimulate absorption, the method consisting in removing 1 c.c. of the exudate and reinjecting it into the subcutaneous tissue. The exudation, however, defies all efforts at removal in about 33 per cent. of the cases, and in such the withdrawal of the liquid by aspiration (thoracentesis) must be practised. The indications for thoracentesis arise at two different periods in the course of pleurisy with effusion:

(1) During the febrile stage, in order to avert imminent danger to life, and not merely to remove the fluid. The conditions demanding immediate thoracentesis are—(a) when one pleural sac is completely filled or when Skoda's resonance extends from the clavicle downward no farther than the second interspace; (b) in double pleurisies, when both sides are half filled, since death may occur from rapid filling of one or the other side; (c) in cases of copious effusions, upon the first signs of involvement of the unaffected side, such as moist râles, broncho-vesicular breathing, and impaired resonance; (d) the appearance of serious symptoms, such as orthopnea or syncopal attacks with cyanosis; (e) marked displacement of the heart, especially if one or more murmurs develop in the organ.

(2) The indications for aspiration during the second or afebrile period, when the main object is to remove the exudate, are—(a) if no

¹ The author has employed this formula in more than 60 cases with very good results.

diminution in the quantity of liquid effusion has taken place one week after the temperature has reached the normal; (b) in subacute cases, in which there is little, if any, temperature from the beginning; aspiration should not then be withheld longer than two weeks.

The operation is free from danger if carried out under antiseptic precautions and if a modern aspirator is employed. The instrument should always be tested before it is used. The patient rests in bed in the semi-recumbent posture, the arm of the affected side being brought forward with the hand placed on the opposite shoulder, so as to separate the ribs from one another. The point of puncture is in the sixth interspace on the right side and the seventh interspace on the left, in the mid-axilla, or just below the outer angle of the scapula in the seventh right and eighth left interspaces, respectively. An assistant draws up the skin from the interspace, while the operator uses the forefinger of his free hand as a director. The needle should be introduced with a quick thrust, hugging the rib below the interspace, but endeavoring to avoid striking its periosteal covering. The fluid may not be obtained at the first operation, and the reasons for this failure are several. The costal pleura may be excessively thickened, or we may meet with a much-thickened fibrous band. Again, the fluid may be encapsulated; and, lastly, the needle may become blocked. Under these circumstances repeated trials should be made. In-aspirable effusion, or *blocked pleurisy* (Mosny and Stern), is ascribed to abnormal rigidity of the sac containing the fluid. Two needles may now be introduced, one of which is the means of injecting sterilized air.

The amount of fluid withdrawn at one time should never be large (3xij to xxiv—384.0–768.0), though a relatively larger quantity may be taken during the febrile stage than during the afebrile, since in the latter instance the lung has been compressed for a longer period of time. The fluid is allowed to drain away slowly, a small needle being used, so as to invite the lung to expand in a gradual manner. If this precaution be not taken, the paretic pulmonary capillaries are apt to become the seat of sudden fresh congestion, followed by edema, and often by a speedily fatal termination. Thoracentesis is to be repeated at intervals of several days if nature does not take up the work of absorption, following the first operations. If during the operation incessant cough, dyspnea, a tendency to syncope, marked thoracic constriction, or sudden intense pain be developed, the needle must be withdrawn instantly.

Thoracentesis should not be resorted to in cases in which croupous pneumonia is associated, and never in very aged and excessively feeble persons. In tuberculous and cancerous pleurisy, Achard and others advise insufflation of unfiltered air as a harmless means of allowing a pleural effusion to be evacuated. Achard uses an ordinary bicycle or other vacuum pump for this purpose.

Holmgren¹ recommends blowing out, instead of aspirating, pleural effusions. Air is pumped in at an opening above to take the place of the effusion as it is forced out below by the pressure of the instreaming air.

(3) **To Support the Strength of the Patient.**—The powers of the system are to be maintained by a nutritious diet, bodily rest, and other hygienic measures. The lighter forms of solid food may be allowed whenever they are found to agree, and it is important to promote the digestive power, if weak, by the administration of suitable remedies.

¹ *Mitteilungen aus den Grenzgebieten der Med. und Chir.*, Jena, xxii., No. 2, p. 173.

During the stage of *convalescence*, therefore, tonics (strychnin, quinin, and arsenic) are to be administered. The dietary should be liberal, though composed of wholesome articles. Gentle exercise in the open air is to be encouraged, and massage of the muscles of the affected side tends to re-establish their usual vigor. To bring about the best possible chest-expansion nothing is so good as light gymnastic exercises, together with the methodical practice of deep inspirations for a minute or two at intervals of three or four hours. The management of the third stage, or that of convalescence, is similar to that of tuberculosis.

EMPYEMA (PURULENT PLEURITIS).

Definition.—A suppurative inflammation of the pleura.

Pathology.—On opening the pleural sac after death we may find a thick, creamy pus, though oftener it is seropurulent and separated into two layers—an upper, clear, greenish-yellow serous, and a lower, thick, purulent layer. In a smaller proportion of cases the exudate is fibrinopurulent. The odor emitted from the purulent collection is either sweetish or fetid (*e. g.*, when due to wounds), and, when the condition is associated with gangrene of the lung or pleura, horribly offensive. *Microscopically* the inflammatory products are identical with those of purulent inflammation in general. The pleural membranes are the seat of a more intense inflammation than in acute serofibrinous pleurisy, and are greatly thickened (1 to 2 mm.). They present a granular suppurating surface, and both visceral and costal pleuræ may exhibit perforations, and the latter, often erosions.

Histologically, the altered membranes consist of new connective tissue, new blood-vessels, and numerous leukocytes.

Etiology.—The following are the chief circumstances under which empyema arises: (1) As a sequel of the acute, sero-fibrinous variety. However clear the effusion may be, it always contains corpuscular elements, which in the further progress of certain cases undergo coincident increase in numbers until the effusion presents a milky aspect, when it is said to be purulent. Thoracentesis may be responsible for this change, though never if performed under rigid aseptic precautions.

(2) In children the effusion early becomes purulent in many instances.

(3) Secondary to the acute and chronic infectious diseases—*blood metastasis*—(pyemia, scarlatina, pneumonia, tuberculosis, and dysentery most frequently; typhoid fever, measles, whooping-cough rarely).

(4) Secondary to malignant affections of contiguous organs (lungs, esophagus), or tuberculous cavities which perforate the pleura. Rarely, carious ribs and vertebræ may cause empyema.

(5) Lymphatic metastasis is probably an important means by which bacteria reach the pleura from neighboring but not contiguous tissues (McFarland).

(6) Injuries to the chest may set up empyema (fracture of the ribs, stab or other penetrating wounds).

Bacteriologic investigation has shown that the organisms most frequently present are the micrococcus lanceolatus (*meta-pneumonia*), streptococcus, staphylococcus, and tubercle bacillus. The cases due to pneumococci usually pursue a favorable course. The leptothrix pulmonalis is often found in putrid effusions.

Clinical History.—The symptoms vary with the cause. The on-

set may be characterized by acute symptoms (*e. g.*, Streptococcus Empyema), such as rigor, followed by high temperature and signal prostration, and in the affected side there may be severe pains, aggravated by deep breathing and bodily movements.

If the exudate becomes gangrenous, a *typhoid state* develops early, and the case is apt to prove fatal in the course of a few weeks. It is quite a common event for the acute symptoms that characterize the invasion to be replaced at the end of a week or more by the more obscure rational symptoms of chronic empyema. The latter, however, may develop very insidiously as a secondary affection. The rational symptoms in a well-marked case should always excite a suspicion of the presence of the affection, but cannot settle the diagnosis. The *local symptoms* (pain, cough, and expectoration) are of a mild character; dyspnea may be more or less intense. I have on more than one occasion found an utter absence of these symptoms. The *general symptoms* are those of septic infection—diurnal chills occurring at irregular intervals, followed by intense paroxysms of fever and profuse sweating—and such patients lose flesh and grow pale and weak. The temperature is higher than in pleurisy with effusion and is intermittently, though irregularly, elevated.

Peptonuria is a symptom of purulent pleurisy that is not without diagnostic value. It, however, also occurs in suppuration associated with the third stage of pulmonary tuberculosis, and in suppuration due to other causes. While not indicative of empyema, it nevertheless serves sometimes to eliminate sero-fibrinous pleurisy. The urine also contains *indican* in excess in the various suppurations, at least from time to time, if not constantly. *Blood examination* invariably shows leukocytosis, often of high degree.

If the pus is not removed artificially, it frequently breaks into the lung, penetrates it, and finally discharges through a bronchus. Pneumothorax now tends to supervene. Traube contends that necrosis of the pulmonary pleura may allow of the soaking of the pus through the spongy lung-tissue into the bronchi, without the establishment of a fistulous connection between the latter and the pleural sac, hence without the formation of pneumothorax. Besides rupture into the lung and external rupture, empyema may perforate neighboring organs (esophagus, pericardium, stomach, peritoneum). In rare instances the pus burrows along the spine behind the peritoneum and the psoas muscle, reaching, finally, the iliac fossa and simulating psoas or lumbar abscess.

Physical Signs.—These are, for the greater part, identical with those of pleurisy with effusion. Attention will therefore be called only to such as are more or less distinctive of the affection. Slight *edema* of the chest-wall over the seat of effusion, especially in children, is often present, and if the pleural sac be not aspirated, the abscess may point externally and evacuate itself spontaneously. In the latter event a *protrusion* between the ribs shows itself: this may be the seat of fluctuation, and present an inflammatory appearance prior to its rupture, with subsequent discharge of its contents. The opening is usually found in the fifth interspace in front, and less frequently in the third and fourth interspaces or below the angle of the scapula behind. The upper level of the fluid does not change so readily on varying the posture of the patient, requiring a longer period of time than in serous effusion.

Baccelli's sign, or the transmission through a serous exudate of the whispered voice, is sometimes an aid in the discrimination of pleurisy with effusion from empyema. According to my own observation, though it is not invariably propagated by large serous exudations of the pleura, it is yet detectable in a large majority of instances, while I have never observed it in empyema.

Certain writers have recently emphasized the importance of recognizing small collections of pus in the pleural cavity, either as complications or sequelæ of pneumonia, scarlatina, typhoid fever, and other infections. Invasion is accompanied by a rigor only in cases in which the infecting organism is the streptococcus. The temperature is irregularly elevated or distinctly septic in character. The leukocyte curve rises promptly as a rule. Of local symptoms, circumscribed tenderness "elicited by pressure of the finger, and at first deeply seated, suggests both the fact of abscess and its location" (Musser). The physical signs of circumscribed effusion are to be sought along the fissures of the lobes and at the bases. A friction-rub is usually audible in the earlier stages.

Pulsating Pleurisy.—Pulsation synchronous with the cardiac beat in pleural effusion has received various designations (*pulsating empyema*, *empyema necessitatis*, *pulsating pleurisy*). The latter term is the most appropriate one, in view of the fact that it occurs not only in empyema necessitatis but also in empyema, which manifests no tendency to point externally and rarely in sero-fibrinous pleurisy.

Its *etiology* is imperfectly known. The principal causes, however, seem to be—(1) a copious effusion; (2) paresis of the intercostal muscles, inducing relaxation of the thoracic wall; (3) a somewhat forcible heart-beat (Henry). The rational *symptoms* of empyema are present. The *physical signs* are also identical with those of the latter affection, with the pulsation superadded. There are instances in which palpation alone detects the systolic pulse in the pleural effusion. With rare exceptions the effusion occupies the left pleural sac. The pulsation may be limited to two or three interspaces, or it may be visible over the entire antero-lateral aspect of the chest; pulsation at the back, however, is rare.

Differential Diagnosis.—An absolute distinction between empyema and *pleurisy with effusion* rests solely upon the results of an aseptic exploratory puncture. For this purpose the needle attached to the ordinary hypodermic syringe, or, preferably, the surgeon's exploring-needle, may be employed, withdrawing but a very small quantity of the fluid, which, if purulent in character, should be examined bacteriologically.

Pulsating pleural effusion simulates closely *aneurysm of the thoracic aorta*. When pulsation occurs in empyema, however, it is seen to be to the left of the normal course of the aorta: the rational symptoms and usual physical signs of purulent pleural effusion are usually present also, while the vascular symptoms and signs of aneurysm of the aorta (thrill, bruit) are absent.

Prognosis.—Empyema is a serious disease, but, obviously, the outlook will be modified by the special etiology. Spontaneous absorption may occur, though it is extremely rare. Rupture into the bronchial tubes is a comparatively favorable event, some cases in which this occurs recovering, while in others death follows in consequence of the sudden inundation of the bronchi. An empyema may, in rarer cases, empty itself externally with favorable issue (*empyema necessitatis*). Evacu-

ation of the pleural cavity is often followed by a continuous discharge of pus for an indefinite period. As a result of the long-continued suppurative process, death may take place by slow asthenia. It must not be forgotten, however, that an unfavorable termination may be, in part at least, ascribable to certain associated affections (phthisis, pericarditis). Double empyema, fortunately a rare condition, is exceedingly grave.

Among children the outlook is much more favorable than among adults. The prognosis has been rendered less serious by the application of surgical principles in the treatment of the disease. In all cases of recovery there is a progressive obliteration of the pleural cavity, owing to adhesions, which finally become universal and lead to marked retraction of the affected side (*pleuritis retrahens*).

Treatment.—The treatment of empyema is chiefly surgical. In a child, especially in empyema following pneumonia, recovery may follow one or more tapplings. In the vast majority of cases, however, free drainage should be provided at the earliest possible moment. The pleural sac should be opened in the fifth or sixth interspace in the mid-axillary line, the incision being from 2 to 3 cm. in length, and if this affords good drainage, nothing more is needed. Resection of a rib (Estlander's operation) may be employed in long-standing cases or in those in which close approximation of the ribs prevents free drainage. Opinions are divided as regards the value of irrigation of the pleural cavity. When the pus emits an offensive odor irrigation with a disinfecting solution is imperative. Carbolic acid should, however, not be used. In rare instances accidents arise during irrigation (sudden collapse, convulsions), and I have observed a dangerous, and in one instance a fatal, collapse as the result of irrigation in a child. For further details in the operative treatment of empyema the reader is referred to textbooks on surgery. Every effort should be made to favor obliteration of the cavity during post-operative treatment. The indication is to bring about the best possible degree of re-expansion of the compressed lung, and in order to accomplish this the method advised by Ralston James has been practised with great success in the surgical wards of the Johns Hopkins Hospital. The patient daily for a certain length of time, increasing gradually with the increase of his strength, transfers water by air-pressure from one bottle to another. The bottles should be large, holding at least a gallon each, and by an arrangement of tubes, as in the Wolff bottle, an expiratory effort of the patient forces the water from one bottle into the other. In this way expansion of the compressed lung is systematically practised. The abscess-cavity is gradually closed, partly by the falling in of the chest-wall and partly by the expansion of the lung.¹ In long-standing cases, in which the lung cannot expand on account of thick bands of adhesion, the pleural layers cannot be brought into juxtaposition without more or less sinking in of the chest-wall. De Lorme's operation (stripping the pseudo-membrane from the compressed lung) may be advisable. This retraction of the thorax is probably hastened by timely resection of one or more ribs, the amount of bone to be removed depending upon the "expansive power of the lung and elasticity of the thorax." The small collections (pleural or interlobar) described above demand prompt drainage.

The duration of empyema is longer than in pleurisy with effusion,

¹ Osler's *Text-book of Medicine*, p. 605.

and the former affection tends to exhaust to a greater degree the powers of the system than the latter; hence the physician's attention should be directed to the support of the vital forces by all possible agencies, modified to some extent by the special etiology of the case.

CHRONIC PLEURISY (ADHESIVE PLEURISY).

Definition.—Chronic inflammation of the pleural layers —(a) with effusion, and (b) without effusion.

(a) **Chronic Pleurisy with Effusion.**—This subvariety may follow acute sero-fibrinous pleurisy, and less frequently it has an insidious development. The morbid lesions, including the character of the exudate, may also be identical with those of the acute or subacute forms of the affection. Fibrin and serum are present in varying relative proportions, the latter, however, in nearly all of the cases preponderating when compared with the composition of the exudate in acute pleurisy. The secondary consequences of copious acute effusions also are met with—*i. e.* displacement of adjacent organs (liver, spleen, heart) and unilateral dilatation of the chest. When the fluid is either absorbed or removed and the case ends in recovery, marked contraction of the affected side results, since the lung, which is covered by thick, organized bands of adhesion, cannot re-expand. *Symptoms.*—But for slight dyspnea upon muscular exercise the subjective symptoms are frequently wanting. The pulse is compressible and accelerated, as a rule, and there is a trifling rise of temperature in the evening hours. If the effusion becomes purulent, hectic fever develops, leading to asthenia, and the latter condition eventually terminates life. Death may also be due to secondary suppurations (abscess of brain, etc.). In most cases occurring in children the effusion early changes to pus. The physical signs do not differ from those in acute sero-fibrinous pleurisy. The *duration* of the cases varies from three months to several years, or intercurrent pulmonary tuberculosis may shorten the course of the affection.

(b) **Chronic Dry or Adhesive Pleurisy.**—(1) This may succeed to the acute or chronic sero-fibrinous pleurisy. If the liquid portion of the exudate is absorbed, the pleural membranes come into more or less close apposition, being separated only by fibrinous elements that become organized into a layer of firm connective tissue. Hence the two layers of the pleura, that are greatly thickened, cannot be separated, owing to the firmness of the adhesions. In most cases the autopsy shows the latter condition to be most pronounced at the base, while the lung is found to be compressed and the seat of fibroid change. If it follows the acute form, the extent of retraction is slight, since there are no dense fibrous bands to prevent a fair degree of lung-expansion; if it succeed the chronic form, however, or empyema, the extent of retraction and flattening will be quite marked. The exudate may undergo calcareous degeneration, and occasionally little pouches of fluid may be found between the false bands.

There is a large class of cases that are dry from the onset (*idiopathic dry chronic pleurisy*), and this variety may either be a sequel of acute plastic pleurisy or primarily tuberculous. The condition is very commonly met with at autopsy in subjects who during life had

never presented symptoms of pleurisy with effusion. The plastic exudate, however slight, invariably tends to become organized, with resulting fibrinous adhesion of the two layers of the pleura. Most generally the adhesions are circumscribed, and if tuberculous in origin are most frequently apical and often bilateral. Under these circumstances small caseous masses and little tubercles may be found embodied in the somewhat thickened pleura. General synechia is, however, not rare, particularly unilateral.

Symptoms.—Definite rational symptoms are rarely present, and the physical signs lack uniformity or may be entirely negative. In other cases of a mild grade the main characteristics are restrained mobility of the affected side and feebleness of the respiratory murmur. In rarer cases the weakness of the breath-sounds is out of all proportion to the expansive motion of the chest. In still another category—composed of a considerable number of instances—certain physical signs are quite pronounced. Inspection reveals decided contraction, with immobility of the affected side and a compensatory distention of the healthy side. The heart is displaced, and the apex-beat may be missing (*e. g.* when the heart is drawn or pushed behind the sternum, or overlapped by the emphysematous lung). The spinal column is curved, the scapula dislocated, the shoulder ill-shapen and drooping, and the lower part of the thorax shrunken, while the ribs are obliquely placed and closely approximated, or even overlap one another. The tactile fremitus is decreased or absent over the lower portion of the chest, and there is impaired percussion-resonance or dulness over this area. The breath-sounds on auscultation are exceedingly feeble, and in some cases an occasional dry, leathery, or creaking friction-sound is audible.

Rarely, and particularly if the case be tuberculous, vasomotor symptoms arise in chronic pleurisy, such as unilateral flushing or sweating of the face, or dilatation of the pupil.

Doubtless some instances of chronic pleurisy merge into the pleurogenous type of cirrhosis of the lung, and fatal complicating conditions may arise in connection with the general circulation. Thus, I have observed in one instance enlargement followed by dilatation of the right ventricle, and in turn by general dropsy, with fatal result.

Treatment.—In the treatment of this affection two objects must receive especial attention: (1) the removal of any effusion that may be present; and (2) the improvement of the nutrition of the patient. The first indication is presented only by a limited number of the cases, and the rules for meeting it have been stated in the treatment of sero-fibrinous pleurisy and empyema; the second indication is presented by all cases. Careful regulation of the diet is of the utmost importance: it must be generous, with modifications to suit special diatheses (as the gouty or tuberculous), if they be present. Lung-gymnastics are most useful if methodically pursued. The method of Ralston James (previously described) richly deserves a trial in suitable cases. It is to be borne in mind, however, that in old cases efforts at overcoming the lung-pressure will be unsuccessful. Climato-therapy is advantageous, particularly if a tendency toward tuberculosis exists; and in my own experience low, mountainous elevations combined with purity of atmosphere have given the best results. Of medicines little need be said. It is

especially important to promote the digestive power of the patient to the greatest possible extent. In cases in which the digestive function has been feeble I have observed excellent results from a brief stay at any well-regulated seaside resort or in the country. We may also use, with a probability that the effect will be beneficial, small doses ($\bar{3}j$ —4.0) of cod-liver oil, three times daily after food, or the following formula:

| | |
|------------------------|---------------------------------|
| R. Acidi muriat. dil., | $\bar{3}ijss$ (10.0); |
| Pepsini pur., | $\bar{3}ij$ (8.0); |
| Tinct. nucis vom., | $\bar{3}iiss$ (6.0); |
| Glycerini, | $\bar{3}iiss$ (46.0); |
| Aquæ, | q. s. ad $\bar{3}ij$ (64.0).—M. |

Sig. $\bar{3}j$ (4.0), well diluted, ten minutes after each meal.

Intercurrent catarrh of the stomach may sooner or later become a troublesome feature, and in combating it lavage is frequently our most effective measure.

PNEUMOTHORAX.

(*Sero-pneumothorax*; *Pyo-pneumothorax*.)

Definition.—A collection of air in the pleural cavity. Since the latter, as a rule, contains at the same time serum or pus, the terms sero- and pyo-pneumothorax are frequently employed to describe the same condition. It is an uncommon condition.

Pathology.—When the pleural sac is punctured air usually escapes, accompanied sometimes by an audible hissing sound. The pleural sac in pure pneumothorax is greatly distended, and the lung is impacted against the spinal column. Other organs (spleen, heart) are also displaced, owing to positive intrathoracic pressure. The heart is not rotated, however, and the relation of its parts is maintained much as in the normal condition (Osler). The air may occupy but a portion of the pleural cavity, on account of previous firm adhesions (*circumscribed pneumothorax*). The point of perforation, as a rule, can be easily found, and frequently corresponds to the seat of rupture of the tuberculous cavity or superficial caseous mass. In other instances the cause of pneumothorax cannot be discovered. Inflation of the lung under water may reveal the aperture, which is usually small, by the escape of air-bubbles at the seat of puncture. Occasionally a fistulous connection between the pleural sac and the bronchi can be traced.

Simple pneumothorax is, however, of rare occurrence. The air that gains admission into the pleural sac is laden with micro-organisms (*vide* Bacteriology, p. 578), which set up various forms of inflammation, accompanied by equally various exudations. Hence the cavity is usually filled, in part, with an effusion that is purulent or sero-purulent, as a rule, and rarely serous or sero-fibrinous. The *gas* in cases of pneumothorax may be of bacterial origin; this contains substances not found in air, such as H, H₂S, or marsh-gas.

Etiology.—The *predisposing* influences are—(a) *age*—the condition occurring in adults, as a rule, though instances are also observed in young children; (b) *sex*—males suffer more than females; (c) the left side is affected nearly twice as often as the right; (d) *emphysema*, in which the superficial air-sacs are dilated and atrophied, and so rendered liable to rupture from excessive muscular exertion.

The **exciting** causes are—(1) *Perforation of the lung and pulmonary pleura* (the most frequent cause), arising in one or other of three ways: (a) From the rupture of a tuberculous cavity into the pleural cavity. This accident rarely occurs at the apex of the lung, but commonly near the upper border of the lower or middle lobe; less frequently near the lower border of the upper lobe. A caseous focus immediately beneath the pleura may also, during the process of softening, puncture the pleural sac and invite the entrance of air during the early stages. It cannot occur, however, except in cases in which previous adhesions have failed to form at the point of perforation. At least 70 per cent. of the cases of pneumothorax are tubercular (Morse).¹ (b) As the result of necrotic processes, in connection with certain other lung-affections, as gangrene, broncho-pneumonia, suppurating bronchial glands, abscess, and echinococcus cysts. (c) From rupture of the normal air-sacs in consequence of severe muscular effort (S. West, DeH. Hall). This accident is sometimes ascribable to the violent paroxysms of cough in pertussis.

(2) Some cases of *empyema*, by perforating the visceral pleura, the lungs, and bronchi.

(3) Perforations of the pleura in *malignant disease* and *abscess of the esophagus*.

(4) A *peripheral bronchiectasis* may open the pleural space.

(5) Pyo-pneumothorax may be of *subdiaphragmatic origin*, consecutive to *perforation by malignant disease* or *ulcer of the stomach or colon*.

(6) Pneumothorax may be occasioned by *gases* resulting from the action of a gas-forming bacterium on the pleural exudate.

(7) *Wounds* causing direct or indirect perforative lesions of the lungs. Fractures of the ribs may produce laceration of the visceral pleura, and allow the air to enter the pleural sac.

Symptoms.—The earliest symptoms vary according to the cause or causes that produce the condition. When it develops, as it does so often, in the course of pulmonary tuberculosis, the *onset* is sudden, marked by agonizing *pain* in the side, by intense *dyspnea*, and frequently *cyanosis*. The dyspnea is often accompanied by a sense of impending suffocation. The severity of the pain and the degree of oppression depend largely, however, upon the amount of air that gains entrance into the pleural sac or is formed from the exudate, the rapidity with which it enters, and the presence or absence of previous pleuritic adhesions. If the orifice be large and valvular, the air cannot escape, but rapidly accumulates and forces all the air out of the lung by compression; the patient then sinks rapidly into collapse from shock, and sudden death ensues. Fortunately, the *open* form is commoner, especially in non-

¹ *American Journal of Medical Sciences*, May, 1900.

tuberculous pulmonary affections. The *respirations* are frequent; the *pulse* is also frequent and feeble, sometimes reduced to a thread; and cold sweats are not uncommon. The *temperature* at first is apt to fall one or two degrees below the normal, owing to sudden collapse; *fever*, however, follows almost invariably, and frequently is of the *hectic* type. Its cause is pleuritis, often purulent, and if this be the case, the dyspnea may be due in part to the increasing effusion. The patient now also suffers from the grave symptoms of empyema above described. Edema of the hand of the affected side is sometimes present

FIG. 49.—1. Air in the pleural sac; 2, fluid exudate at base of pleural sac; 3, compressed portion of lung; 4, displaced heart; 5, depressed spleen; 6, mediastinum pushed toward the right.

as an early manifestation; it rapidly disappears (Weil). When pneumothorax develops in the last stages of phthisis acute symptoms may be entirely absent.

Physical Signs.—These are marked (see Fig. 49), although rarely they may be in abeyance for several days (masked pneumothorax). *Inspection* shows marked distention and immobility of the affected side; also some degree of distention with unnatural mobility of the healthy side.

Palpation shows the tactile fremitus to be diminished above and greatly diminished or wholly absent over the effusion below. Edema of the chest-wall can frequently be made out. The impulse-beat of the heart is found to be feeble and displaced.

On *percussion* a deep and full, or modified tympanitic note (*bell-tympany*) can usually be elicited over the area corresponding to the contained air, and the excessive tension in the pleural sac, due to the enormous amount of air it contains, may cause an elevation in the pitch of the note even to dulness. The "cracked-pot" sound is audible when the air in the pleural cavity freely communicates with the external air. Wintrich's sign, or a change in the pitch of the percussion-sound when the mouth is open or closed (being lowered when the mouth is closed and raised when open), may also be observed. In pyo-pneumothorax a flat note is elicited from the base upward as far as the fluid extends, and change of posture causes a more marked temporary variation in the upper level of flatness than occurs in pleurisy. Modifications in the pitch of the percussion-sound result from an alteration in the form as well as in the dimensions of the air-space. Owing to displacement of the heart, there is, as a rule, resonance over the normal cardiac region, and particularly when the patient assumes a recumbent posture. The liver and spleen, according to the side affected, are displaced downward to a greater degree than in simple pleuritic exudates.

Auscultation discloses a greatly weakened or altogether suppressed respiratory murmur when collapse of the lung is incomplete. Amphoric breathing is audible in cases of *open* pneumothorax, and bronchial râles possessing a metallic quality are sometimes heard, as well as metallic tinkling on deep inspiration or on coughing. The metallic tinkling is caused frequently by drops of fluid falling from above upon the surface of the effusion; less frequently by a re-echoing of vibrations of moist bronchial râles communicated to the air in the pleural chamber. The vocal resonance is enfeebled, as a rule, and evinces the same metallic quality. The so-called coin-test is a pathognomonic sign, and is elicited in the following manner: An assistant places one coin on the front of the chest and taps it with another while the ear of the examiner is placed on the thorax posteriorly, where will be heard the intensified echo of the coin-sound thus produced. Another most characteristic sign is the so-called Hippocratic succussion, which is elicited by placing one ear upon the patient's chest while the latter's body is shaken, a distinct splashing sound is heard.

Diagnosis.—When the attack is of ordinary severity, pneumothorax is diagnosticated by the history of one or other of the causal factors, together with certain physical signs that do not belong to any other affection (*coin-sound, succussion-splash*). The sputum test and also bacteriologic study of the aspirated purulent exudate with a view to determining the special etiologic variety present in a given case is of the greatest importance. It is only when the air and fluid in the pleural sac are encapsulated that it may become difficult to eliminate (*a*) a large pulmonary cavity; (*b*) excessive gaseous distention of the stomach; (*c*) an abscess below the diaphragm into which air has entered (*pyopneumothorax subphrenicus*); (*d*) a diaphragmatic hernia; (*e*) emphysema; and (*f*) pleurisy with effusion.

(a) *A Large Pulmonary Cavity*.—The “cracked-pot sound” and Wintrich’s sign are more frequent in cavity than in pneumothorax, and the former condition does not tend to dislocate the adjacent organs. There is an absence of the succussion-splash, and, except in rare instances of the coin test, these signs are often present, even in circumscribed pyopneumothorax. Tabulated, these points of difference are—

PYO-PNEUMOTHORAX.

Immobility and bulging of the interspaces. The apex-beat is usually displaced.

Diminished vocal fremitus.

Percussion-note deep and full. The effusion sinks to the base, and yields flatness, the outline of which changes with the posture of the patient.

Respiratory murmur and vocal resonance usually absent. Amphoric breathing may be heard if the opening in the lung is patulous. The coin-sound and Hippocratic succussion-splash are noted.

LARGE PULMONARY CAVITY.

Immobility, flattening of the chest, and depression of the interspaces. Apex-beat not displaced.

Fremitus usually increased.

Percussion gives tympany or a “cracked-pot sound,” and Wintrich’s change of sound as a rule.

Bronchial breathing is heard, and the vocal resonance is increased. Crackling, gurgling râles, cavernous or amphoric breathing, and pectoriloquy may be present. Absence of bell-tympany (generally) and succussion-splash.

(b) *Excessive gaseous distention of the stomach* is to be eliminated by the history of the case and by the results of the application of the therapeutic test, evacuation of the stomach and bowels.

(c) *Subphrenic Abscess Containing Air*.—This is exceedingly rare, and occurs relatively oftener on the right than on the left side (Leyden). Its leading causes are ulcers of the stomach or duodenum, followed by circumscribed peritonitis, perforation, and abscess, the latter occupying a position immediately beneath the diaphragm and above the liver. The gases that gain admission to the abscess-sac from the intestines force the diaphragm upward, and thus cause retraction or even compression of the lung. The symptoms are now identical with those of circumscribed pyo-pneumothorax, limited to the base. A knowledge of the steps in the production of subphrenic abscess; the absence of cough and expectoration, and of marked displacement of the heart; and the presence of bulging of the hypochondrium, of striking depression of the liver, and of Pfuhl’s sign (*q. v.*), are indications favoring subphrenic abscess.

(d) *Diaphragmatic Hernia*.—This either results from a severe injury or is congenital, and the most valuable point of difference between hernia of the diaphragm and pneumothorax is the peculiar cause of the former. The next most valuable point is the fact that the hernial protrusion may return suddenly to its normal position, whereupon the patient will be relieved; the condition may then reappear not less suddenly. The third distinctive feature is the presence of rumbling sounds in the protruded bowel. All other signs and symptoms of one affection may have their counterparts in those of the other.

(e) Pneumothorax may be confounded with *emphysema* by the careless observer; but the latter affection is slow in onset, free from serious shock, is bilateral as a rule, and does not exhibit the distinctive physical

signs of pneumothorax (metallic tinkling, coin-sound, succussion-splash). In *pleurisy with effusion* hyper-resonance may be noted above the fluid, but it lacks the bell-like tympany of pneumothorax. Over the same area there is diffuse, distant, bronchial breathing (at times slightly amphoric), whilst the metallic tinkling, coin-sound, and succussion-splash are totally wanting.

Prognosis.—This depends largely upon the cause. The cases attributed to advanced phthisis usually reach a fatal issue in the course of one, two, or more weeks, and rarely they run a very rapid and fatal course. On the other hand, the pulmonary condition is at times favorably influenced by its occurrence. Following empyema, or when due to trauma or abscess of lung, pneumothorax sometimes takes a favorable course. It is fraught with especial danger when it is the resultant condition of some acute lung disease (gangrene, broncho-pneumonia). The prognosis is worse in right-sided pneumothorax.

Treatment.—The leading indication is the alleviation of the patient's sufferings by a prompt resort to morphin, and it often becomes necessary to administer it hypodermically. If the patient's previous strength has been moderately good, the question of operative intervention should be seriously considered, the nature of the surgical procedure then depending upon the character of the effusion. If this be sero-fibrinous, aspiration, as in simple pleurisy, must be performed to relieve the urgent dyspnea; if purulent, permanent drainage should be procured for the same indication. A costal resection may be advisable. When pneumothorax develops late in phthisis radical measures are not to be thought of, and the physician must rely upon aspiration (when necessary) to relieve urgent symptoms. We may also tap the air-chamber above the fluid with a fine needle, with a view to lessening the excessive tension. Unverricht has recently reported good results from a somewhat novel mode of treatment. When there is a pulmonary fistula present, he inserts a tube into the pleural sac. This allows free entrance of air, the lung collapses completely, and the fistula has a chance to heal. For the dyspnea, atropin administered hypodermically is valuable; for the feeble cardiac action, alcoholic stimulants, aromatic spirits of ammonia, strychnin, ether, and other cardiac stimulants should be employed. Locally, cutaneous irritants may be applied (turpentine stupes, mustard pastes).

HYDROTHORAX.

(*Dropsy of the Pleura; Thoracic Dropsy*).

Definition.—A collection of transuded serum in the pleural cavity.

Pathology.—Hydrothorax is generally a bilateral condition. The transudate is a clear, amber-colored liquid that is free from fibrin, but may contain cholesterin and a few endothelial cells. It has an alkaline reaction, a comparatively low specific gravity (1009 to 1012), and is non-inflammatory. The pleural surfaces are usually smooth, though some-

times decidedly pale and edematous. The mechanical effects of hydrothorax upon the lungs and other thoracic and abdominal viscera are similar to those of the exudates that accompany inflammation of the pleura, though they are rarely so marked as in sero-fibrinous pleurisy.

Etiology.—Hydrothorax is a secondary affection, and is usually connected with one or other of the various forms of general dropsy (hemic, renal, cardiac). The cases that are due to blood-impoverishment are more numerous than is generally indicated by writers upon the subject, and not infrequently is hydrothorax secondary to either chronic dysentery, chronic diarrhea, leukemia, pernicious anemia, carcinoma, malaria, syphilis, or scurvy. Strictly local causes may also induce it, as carcinoma of the pleura, or the compression of the superior vena cava or of the thoracic duct by a tumor. Fetterolf and Landis have demonstrated that the fluid comes from the visceral, and not the parietal, pleura, including the azygos veins.

Symptoms.—The *subjective symptoms* are attributed to the mechanical effects of the fluid, and may be quite in common with those of the causal affection; these are *dyspnea* (often culminating in orthopnea), *cyanosis*, *asthmatic seizures*, *irritative cough*, and a *feeble circulation*. The *general symptoms* arise from the primary affection.

Physical Signs.—The physical signs are much the same as in pleurisy with effusion—with this difference, that they are more often bilateral. Hydrothorax is often unilateral, however, and an enlarged right auricle may be the cause of this condition in some instances. The right side is the one usually affected. I have also observed that quite frequently the two sides of the chest exhibit great variations as to the relative amount of fluid contained.¹

Prognosis.—This depends upon the nature of the primary disorder that causes the dropsical transudation.

Treatment.—The treatment of hydrothorax has intimate relations with the indications presented by the underlying affection. If the measures directed toward the removal of the general dropsy (*anasarca*), of which hydrothorax is a part, are unsuccessful, and the amount of transudation in the pleural sac interferes with the functions of the heart and lungs, then aspiration must not be too long delayed, and must be repeated as often as occasion demands.

NEW GROWTHS OF THE PLEURA.

ALMOST all instances of new growths developing in the pleura are secondary to primary carcinoma of the lung, the pleura being invaded by the direct extension of the neoplasm. It may also arise by metastasis from carcinoma of the lung, mammary glands, etc. The pleura presents circumscribed areas of thickening, or the growth takes the form of papular projections from its surface, becoming pedunculated as they enlarge. Their size varies from that of a pea to that of an orange. The adjacent pleura is inflamed, often adherent, and much thickened, and an effusion into the pleural cavity is often observed.

Primary carcinoma of the pleura is very rare indeed, and E. Wag-

¹ For the differential diagnosis between pleurisy and hydrothorax, see Pleurisy, p. 591.

ner, who first described it, called it endothelial carcinoma. Most pathologists of to-day, however, look upon endothelioma as a variety of *sarcoma*. It owes its origin to a proliferation of the endothelial cells of the connective tissue and the lymph-apparatus of the pleura. This invariably assumes the diffuse form, and by metastasis we have involvement of the other organs (lungs, lymphatics, liver).

Spindle-cell sarcoma of the pleura, as well as the round-cell variety, is occasionally met with.

Symptoms.—The subjective symptoms are slight in cases in which there is a single circumscribed carcinomatous mass in the pleura; but they are quite severe in the diffuse form, particularly when, as commonly occurs, it is of a secondary nature. The symptoms are now those of plastic or sero-fibrinous pleurisy, in addition to those of primary carcinoma of the lung, and the former may oftentimes more or less completely overshadow the latter.

Diagnosis.—The circumstances under which the condition arises often throw the strongest light upon its nature. The symptoms of slowly developing pleurisy, either plastic or sero-fibrinous, following carcinoma of the lung or the breast, and accompanied by the cancerous cachexia, would point strongly to the existence of *carcinoma of the pleura*. Characteristic cancerous elements may also be found by microscopic examination of the usually hemorrhagic fluid obtained on aspiration. The exudate contains fatty endothelial cells.

The difficulties surrounding the diagnosis of primary carcinoma of the pleura are great and usually insurmountable. The cases are very similar in their clinical manifestations to *chronic pleurisy with or without effusion*. Pain is always a more prominent symptom, however, than in simple chronic pleurisy, and this fact, when combined with evidences of a cancerous cachexia, should excite strong suspicions.

The prognosis is wholly unfavorable, and the treatment merely palliative.

DISEASES OF THE MEDIASTINUM.

THE affections of the mediastinum may be divided into four classes: (a) Inflammation, (b) Tumors, (c) Diseases of the thymus gland, and (d) Mediastinal hemorrhage.

(a) **Inflammation.**—This may affect (1) the glands or (2) the connective tissue. **Lymphadenitis** of moderate grade is found in association with broncho-pneumonia and the various forms of bronchitis. The condition appears in its most pronounced form in the bronchitis of measles, influenza, and whooping-cough, and De Mussy held that enlargement of the glands in the posterior mediastinum is potent in exciting paroxysms of whooping-cough. According to De Mussy and Guitéras, these glands when greatly enlarged give rise to dulness in the upper part of the interscapular region or down to the fourth dorsal vertebra in cases of influenza and whooping-cough. I have, moreover, been able to confirm this dictum in cases of influenza, though aware of the fact that

many authorities consider it questionable. Tuberculous lymphadenitis is elsewhere described (*vide* Tuberculosis, page 243). The mediastinal lymph-glands may undergo suppuration in consequence of local specific infection, and though not recognizable during life, the condition may lead to perforation into either the esophagus or a bronchus, with serious results. In other instances spontaneous absorption occurs, leaving behind inspissated contents that undergo calcareous change.

Abscess of the Mediastinum.—This is of rare occurrence, its most frequent seat being the anterior mediastinum. Of the commoner causes may be mentioned traumatism and the infectious diseases—erysipelas, rheumatism, measles, and small-pox in particular. It may also be the result of an extension of a suppurative process from neighboring structures. Pulmonary tuberculosis is the most potent factor in producing chronic abscess in this situation.

Symptoms.—*Acute Abscess.*—Pain and tenderness in the sternum are the most prominent features, the pain being acute and often of a throbbing character. Cough and dyspnea are usually present. The general features are fever, frequently accompanied by rigors, profuse sweats, and prostration. The chief physical sign is dulness upon *percussion*, usually found anteriorly and increasing gradually with the development of the abscess. Later, the tumor may reach the surface of the body, and rarely the sternum is eroded. *Palpation* now detects pulsation and fluctuation. The abscess may either find its way downward into the abdomen, or it may perforate the trachea or the esophagus.

In *chronic abscess* the symptoms bear a closer similarity to those of solid tumors than do those in the acute form. Fortunately, chronic abscess quite often results in spontaneous cure, in which case it is in part absorbed, and the remainder of its contents become inspissated.

Diagnosis.—*Acute abscess* must be differentiated from solid mediastinal tumors and aneurysm. The more acute onset and general symptoms of the suppurative process (hectic type of fever, chills, sweats) and the more rapid course will serve to distinguish abscess from *aneurysm* on the one hand, and *solid tumors* on the other. Further, the absence of strong expansile pulsation, diastolic shock, and the aneurysmal bruit aid materially in eliminating *aneurysm of the arch*. In obscure cases an exploratory puncture with a small needle may be safely practised, and, as a rule, with definite results.

The **treatment** is mainly surgical.

(b) **Tumors of the Mediastinum.**—Two forms only demand practical consideration—carcinoma and sarcoma. Hare's analysis of 520 cases gave the following ratio: of carcinoma, 134; sarcoma, 98; lymphoma, 21; fibroma, 7; dermoid cyst, 11; hydatid cyst, 8; and fewer cases of ecchondroma, lipoma, and gumma. In 48 of the cases of carcinoma and in 33 of sarcoma the tumor occupied only the anterior mediastinum. It is quite probable, however, that sarcoma, and not carcinoma, is the commoner neoplasm of this region. The clinical term "cancer" was formerly used promiscuously by many authors, and the pathologic diagnosis was then difficult, so that statistics are scarcely trustworthy. Upon investigating 25 of the older reports of "cancer," Pepper and Stengel found

in 13 unquestionable evidence that the growth was sarcoma, while in the remaining 12 they could not, for the greater part, decide to which form the disease belonged. Primary sarcoma may spring from the remnant of the thymus gland, from the lymphatic glands, the pleura, or lungs, or from the fibrous tissues of the mediastinum. Primary carcinoma may originate in the esophagus, bronchi, lungs, or rarely in the thymus gland. Secondary mediastinal tumors are most apt to have their seat in the lymphatic glands. Carcinoma is less frequently primary than sarcoma. Among *predisposing causes* are sex and age—males being more prone to the affection than females, and the period of chief liability is between the thirtieth and fortieth years.

Symptoms.—The earlier symptoms are vague (slight substernal pains, dyspnea, general languor). Later, pressure-symptoms gradually supervene.

The *pain* may or may not be severe, but is invariably accompanied by a feeling of oppression. Its chief seat is in the upper sternal region, but it may radiate to the sides of the chest and even down the arms (in which case it is due to pressure on the brachial plexus). *Dyspnea* appears early, is constant, and may become intense. It is caused by pressure either upon the trachea, upon a primary bronchus, or upon a recurrent laryngeal nerve. *Asthmatic seizures* may occur before there is constant dyspnea and before the tumor has reached notable size. There is *cough*, which may be paroxysmal and of a brazen character. Aphonia may be present. There may be *dysphagia* from pressure upon the esophagus, though this is rare. If there is an inflammation of the vagus or sympathetic nerve, the rate of the pulse may be either slowed or markedly quickened. Owing to implication of the sympathetic there may be local hyperemias and pupillary inequalities.

Compression of the superior vena cava or of the subclavian vein may be followed by cyanosis and edema of the parts drained by these vessels, and the early occurrence of venous occlusion and marked dilatation of the superficial veins is quite characteristic. Collateral circulation may be rarely established. Less frequently the inferior cava may also be compressed.

Physical Signs.—*Inspection.*—In advanced cases a swelling, usually somewhat irregular and often diffuse, appears in the sternal region. The tumor may cause erosion of the sternum, and a little later occupy a position immediately beneath the skin, Osler¹ being of the opinion that the rapidly-growing lymphoid tumors, more commonly than others, perforate the chest-wall. I saw a case in which the perforation occurred at the right edge of the sternum, precisely at the point at which aneurysms of the ascending arch most frequently appear. In the early stages, however, this prominence is not present. *Palpation.*—When a tumor is present it may pulsate distinctly, and the heart's apical impulse may be detected in various abnormal positions. Tactile fremitus is feeble or absent over the seat of the growth.

On *percussion* dulness is noted, and this is true even in many instances that do not present a visible swelling. The dull area varies in outline

¹ *Practice of Medicine*, p. 579.

with the size and position of the tumor. *Auscultation* usually reveals no sounds over the dull area, except a bruit in rare instances. The heart-sounds are inaudible over the tumor-site as a rule, and the breath-sounds and vocal resonance are feeble or absent. To the above physical signs are frequently added those of pleural effusion.

The **diagnosis** of mediastinal growths is made, if at all, principally by exclusion.

Aneurysm is differentiated from solid mediastinal tumors with only slight success in many instances. It is most valuable to note carefully the length of time the condition has lasted, since aneurysm runs a longer course, on the average, than mediastinal tumor. The tumor when due to aneurysm communicates a strong, heaving, expansile pulsation—a characteristic that is absent or only feebly manifested in the case of solid mediastinal growths. The severe diastolic shock, noted on both palpation and auscultation in cases of aneurysm, is also absent in solid tumor. Kassabian has shown that new growths can be early recognized by an *x-ray* examination. On the other hand, shadows situated in the anterior portion of the chest and to the right of the median line are generally produced by aneurysms.

The *duration* of the disease varies from six to eighteen months.

The **prognosis** is absolutely hopeless, except in the case of benign tumors, which may be removed in some instances.

The **treatment** is directed toward the relief of the most urgent symptoms. Anodynes are required sooner or later, and should not be withheld if indicated. As a routine the preparations of iodine and mercury are employed; but, as these are useless, they are unwarranted. Arsenic has sometimes seemed to influence sarcomatous and lymphadenomatous growths favorably, though only temporarily.

(c) **Diseases of the Thymus Gland.**—Nothing is known definitely concerning the functions of the thymus gland. Tumors may have their origin in the thymus gland, and the organ may become enlarged (hypertrophy, abscess); these conditions are indistinguishable from and associated with mediastinal tumor or abscess as above described.

Jacobi believes that fatal cases of laryngismus stridulus may be rarely ascribable to an enlargement of the thymus gland. C. H. Hunter¹ reports two cases of primary fatal laryngeal stenosis occurring in the same family in children aged 19 and 7 months respectively. The question as to the existence of the so-called asthma thymicum, however, is still *sub judice*, although the number of sudden deaths in young children reported in connection with various forms of enlargement of the thymus gland is steadily increasing. Arnold Paltauf attributes sudden death in cases in which the thymus was found enlarged to hyperplasia of the entire lymphatic system (*constitutio lymphatica*). Olmacher² noted in 18 cases of epilepsy a large and apparently functionally active thymus gland. There was hyperplasia of the lymph-glands throughout the body and of the lymph-follicles of the mucous surfaces.

Symptoms.—These indicate stenosis of the air tract. There is inspiratory and expiratory stridor, as a more or less audible whistling respiration (Schwinn). Among *physical signs* are—inspiratory dilation of

¹ *British Med. Jour.*, April 2, 1898.

² *Phila. Med. Jour.*, Jan. 1, 1898; Saunders' *Year-Book* for 1899.

the nostrils, cyanosis and marked retraction of the supraclavicular, infraclavicular, and intercostal spaces. In other instances, the symptoms of suffocation precede the fatal termination. Potts reports four cases where children died in this manner within two minutes after the insertion of a tongue depressor. For diagnostic purposes a radiographic examination gives trustworthy results.

Persons who manifest the hemorrhagic diathesis, or those who suffer from hemorrhagic affections, may also show hemorrhage into the thymus gland—a condition that is identical with that produced by hemorrhage into the mediastinum. Operation with the view of removing the offending organ should be undertaken, although there are cases in which the child expires before medical aid can be procured. Siegel, in one case, a boy of $2\frac{1}{2}$ years, elevated and stitched the thymus to the fascia over the sternum, with the result that the threatening dyspnea disappeared and the child eventually made a good recovery.

(*d*) **Mediastinal Hemorrhage.**—This term signifies hemorrhage into the mediastinal connective tissue. It oftenest results from the rupture of aneurysms of the arch or of the large vessels within the thorax. It may be of traumatic origin (wounds, fractures).

PART VI.

DISEASES OF THE CIRCULATORY SYSTEM.

I. DISEASES OF THE PERICARDIUM.

PERICARDITIS.

Definition.—An inflammation of the serous covering of the heart.

Varieties.—(a) Plastic, or fibrinous; (b) sero-fibrinous, or subacute; (c) purulent; (d) hemorrhagic; (e) adhesive. There is also a tuberculous pericarditis which has been described (*vide* Tuberculosis, page 279).

Bacteriology.—Rudini's experiments have shown that the staphylococcus aureus may be a cause of pericarditis; but they have not conclusively demonstrated that it is the specific cause, as is evidenced by the fact that the disease is sometimes caused by other organisms. Moreover, staphylococci have not been encountered without demonstrable cause. Among other organisms, the pneumococcus, streptococcus, the bacillus coli, the tubercle bacillus, and probably also a variety of the bacillus pyocyaneus and the gonococcus may be named. Microorganisms are not always found in pericarditic exudates.

ACUTE PLASTIC OR FIBRINOUS PERICARDITIS.

Pathology.—The morbid changes are frequently localized, and less frequently are general. At the onset the membrane is smooth, swollen, and injected, and punctate ecchymotic spots may be visible; soon it presents a grayish, roughened appearance from the deposit of a thin layer of fibrin. In the severer types the fibrinous deposit increases in thickness for a time, and the natural movements of the pericardial surfaces upon one another sometimes cause the exudate to assume a honey-combed appearance. Most examples that I have seen, however, have resembled the roughened surfaces produced by separating two slices of thickly-buttered bread; the surfaces are grayish-yellow in color. In the later stages the exudation becomes partly organized, and, as the result of friction produced between the opposed surfaces by the incessant action of the heart, may present a villous appearance; hence the term "hairy heart" of the ancient authors. For like reasons we may see the exudate arranged in the form of little ridges, forming a "tripe-like membrane."

Though invariably present, the amount of serous effusion, as the term would indicate, is never large in dry or plastic pericarditis. Myocarditis may frequently be found as an associated condition.

Etiology.—In each variety of pericarditis there are special contributing factors, so that it is desirable to give its etiology separately, except in the sero-fibrinous and acute plastic types, which have practically the same etiology. The two latter are the more common forms of the disease. Acute plastic pericarditis most frequently occurs in young and middle-aged males. It may be *primary* or *secondary*. It often occurs in acute articular rheumatism (in more than one-half the cases), chorea, lobar pneumonia, chronic nephritis, and, rarely, in other acute infectious diseases. In this form the infective agents are transmitted to the pericardium by means of the circulation. It may be caused also by direct extension of inflammation from adjacent structures (secondary pericarditis), as in simple pleurisy; more commonly the extension occurs from a pneumonia or tuberculous pleurisy, or the condition may complicate new growths and inflammatory conditions affecting the esophagus and bronchial glands. It may also be secondary to chronic disease of the aortic valve, the pericardium becoming involved by extension through the walls of the aorta. Finally, it may be the result of traumatism, and this may cause any of the other forms of pericarditis.

Clinical History.—Owing to the fact that acute plastic pericarditis is usually a secondary affection, the symptoms that enable one to recognize it are obscured by those of the primary disease. This is particularly true of that large class of cases that develop in acute articular rheumatism, in which subjective symptoms are often entirely wanting. Only in the severest types of this sort are the symptoms referable to the heart well enough marked to arrest the attention. There may be a feeling of *distress* or *constriction* with or without slight *pain* in the precordium. During the first stage or prior to the pouring out of the effusion the pain is most marked, extending sometimes into the left arm or the back, and at others to the ensiform cartilage or even to the abdomen. This pain is, rarely, increased by pressure over the precordia. *Palpitation* and *dyspnea* may be present, and the *pulse* is increased in frequency and strength, as a rule, except in the later period, when it may be weak and slightly irregular, particularly if the muscular tissue of the heart be involved. There is some *fever*, but the degree of elevation of temperature perhaps never exceeds 102° F. (38.8° C.). In this class of cases the *urinary features* depend largely upon the character of the leading etiologic factors; though in many instances the urine is scanty, high-colored, and acid in reaction.

Physical Signs.—*Inspection* discloses increased vigor of the apex-beat. Friction-fremitus (due to rubbing of the altered pericardial layers upon one another) may sometimes be felt during the earlier and later courses of the disease or when the membrane is comparatively dry, and is usually most intense near the base, just to the left of the sternum. *Percussion* gives negative results. *Auscultation* usually reveals a double friction-sound, sometimes quadruple (locomotive murmur)—the most important sign for a positive diagnosis. The friction-rub is caused partly by the exudate and partly by the dry state of the membrane. Its usual seat of maximum intensity is in the fourth and fifth interspaces and the
